1.12.1 Introduction

With the development of large seismic networks, huge quantities of continuous recordings have been made available. The extraction of deterministic information about Earth's structure from long ambient-noise time series opens up new opportunities for seismologists. Correlations of ambient seismic vibrations are widely and effectively used to reconstruct impulse responses between two passive receivers as if a source was placed at one of them. This provides the opportunity for imaging without a source, or passive imaging. Applications include seismology, helioseismology, underwater acoustics, and structural health monitoring, to cite only a few. This chapter offers a brief presentation of the principles leading to the use of seismic ambient-noise correlations as virtual seismograms that correspond to the responses of the earth between two stations. While the correlation technique saw great developments in seismology in the 2000s, the interest in this kind of approach had already been stated in earlier studies, such as those of Aki (1957) and Claerbout (1968). Indeed, the same principles have been successfully applied in helioseismology (Duvall et al., 1993). The literature on the subject has grown rapidly, and it would be difficult to include all the approaches in this summary. Courtland (2008) reviewed the recent emergence of the method in seismology. Some review papers have already been published (e.g., Campillo, 2006; Gouédard et al., 2008b; Larose et al., 2006b; Wapenaar et al., 2010a,b). The reader can also refer to the book by Sato et al. (2012). This chapter focuses mostly on ambient noise in seismology, while the correlation methods have also undergone important developments with the construction of virtual seismograms from active-source records in exploration (e.g., Curtis and Halliday, 2010; Rickett and Claerbout, 1999; Schuster, 2006; Wapenaar et al., 2010a,b).

In **Section 1.12.2**, a brief overview of the nature of the ambient noise in the relevant frequency band for broadband seismometer records is presented. The correlation method

 http://dx.doi.org/10.1016/B978-0-444-53802-4.00024-5

through heuristic approaches is introduced in Section 1.12.3. Some mathematical results for simple media or simple noise–source distributions are given in Section 1.12.4. The limitations of the approach in actual situations are discussed in Section 1.12.5. The strategies of processing are presented in Section 1.12.6, and examples of applications to imaging and monitoring are presented in Section 1.12.7.

1.12.2 Noise Origin

Some aspects that are important for the applications discussed in the following sections are recalled here. Seismic ambient noise has been studied since the beginning of seismology, largely because of the need to improve the level of detection of deterministic arrivals. From early studies (e.g., Gutenberg, 1958), it was recognized that the origin of the permanent agitation of the ground surface is different for different frequency bands. The high-frequency noise ($f > 1$ Hz) is generally due to human activity (e.g., machinery, traffic). The energy of these signals is strongly variable in time, and is correlated with human life rhythms, with day and week periodicities. On the contrary, the natural origin of long-period ambient noise was recognized through the correlation of the amplitude with meteorological conditions. The frequency limiting the domain of human activity is dependent on local conditions (e.g., Bonnefoy-Claudet et al., 2006). As no generalities can be drawn for high-frequency noise, this discussion concentrates on a low-frequency band that is well defined globally as associated with the interaction of the oceanic swell with the solid Earth. In the band of 0.3–0.05 Hz, the ambient noise is often referred to as 'microseisms.' Note that the general issues discussed in the following sections for the correlation of microseism records also apply for anthropic noise at high frequency. Microseisms have large amplitudes that provide an obstacle for the detection of weak arrivals produced by earthquakes. As the detectability level is an important issue in seismology, microseisms have been extensively studied. In the microseism spectral band, the noise is dominated by surface waves, which are predominantly Rayleigh waves (e.g., Toksöz and Lacoss, 1968). The presence of body waves has nevertheless been attested (e.g., Vinnik, 1973). The coincidence of periods of strong microseisms and high swells that reach the coastline was noted early on (Gutenberg and Mainka, 1924). Toksöz and Lacoss (1968) used array analysis to demonstrate the correlation between microseism sources and regions of low atmospheric pressure.

Two peaks dominate the spectrum of microseisms, the principal one being for a period between 5 and 7 s, while a less marked peak is observed at twice the period of the main peak (e.g., Peterson, 1993). These general characteristics are interpreted as the footprint of the spectrum of oceanic gravity waves.

The less energetic single-frequency or primary microseism peak, at periods around 14 s, is similar to the spectrum of wind-generated ocean gravity waves (Haubrich et al., 1963). With the limited penetration of gravity waves at this period, the noise is expected to be produced in shallow waters and to be amplified by shoaling. To decipher the geographical origin of the primary microseism, Stehly et al. (2006) analyzed the energy of long-term average noise cross-correlations as a function of the azimuth of the station direction. The distribution of sources shares a great similarity with the map of average ocean wave heights obtained from satellite observations, which shows zones of primary microseism excitation in oceanic deep basins, with a seasonality of the global contributions from northern and southern oceans.

The stronger double-frequency or secondary microseism peak at a period around 7 s is interpreted as the result of nonlinear interactions between ocean gravity waves propagating in opposite directions, as shown by Longuet-Higgins (1950) based on earlier studies of Miche (1944). This nonlinear process produces a pressure at the sea bottom, even when the height of the water column is greater than the gravity-wave wavelength. The amplitude of the excitation depends on the response of the resonant water layer for specific periods and bathymetry. The microseism excitation depends on the ocean-wave state (swell amplitude), the existence of wave trains in opposite directions, and the bathymetry (resonance condition). The existence of gravity waves that propagate in opposite directions can be due either to reflection along the coast or to specific conditions of storm systems in the deep oceanic basins (e.g., Kedar et al, 2008; Zhang et al., 2010). Teleseismic body waves are identified using beam forming, by their high apparent velocity, and they have been used to map the actual sources in the oceans (e.g., Landès et al., 2010). Recent analyses have suggested that both coastal and deepwater origins are represented in the actual observations (Ardhuin et al., 2011; Hillers et al., 2012), and it has been demonstrated that global oceanographic models of sea state coupled with the physical description of the excitation allow for independent prediction of the main patterns of secondary microseism sources.

At long periods, that is, below 50 s, the ambient noise that is often referred to as hum has the spectral structure of the free oscillations of Earth (e.g., Kobayashi and Nishida, 1998; Tanimoto et al., 1998). The origin of this excitation is assumed to be the interaction of the ocean infragravity waves with the solid Earth. This mechanism was confirmed by the correlation between the apparent locations of hum sources and regions of large wave heights (e.g., Rhie and Romanowicz, 2004). Nishida et al. (2008a) showed that the generation of background ambient noise at long periods occurs both in coastal regions and in deep oceans. The normal pressure caused by oceanic waves on the sea bottom can account for spheroidal motions. However, large toroidal contributions (e.g., Kurrle and Widmer-Schnidrig, 2008) and long-period Love waves (Nishida et al., 2008a) have been observed. This was explained by Fukao et al. (2010), who proposed a model for the coupling of infragravity waves with the topography of the sea bottom.

To conclude this short presentation, it appears that the origin of the seismic ambient noise is still the object of ongoing research and discussion. Different processes are invoked exclusively for the two main spectral peaks and the long-period domain in spite of the continuous character of the noise spectrum.

1.12.3 Principle of the Method: The Heuristic Approach

In this section, simple physical views of the principle of the ambient-noise correlation method are presented. The mathematical developments are discussed in the next section.

The results presented here originate from previous studies in seismology that were aimed at using ambient noise to extract deterministic information relating to Earth's structure (e.g., Aki, 1957; Claerbout, 1968). In seismic exploration, the 'daylight imaging' method was pioneered by Claerbout (1968), who proposed the conjecture stating that the cross-correlation of two daylight traces at surface locations A and B is equivalent to a reflection trace at B generated by a source at A. A formal demonstration was given for the one-dimensional (1D) case. The same idea was then successfully applied in time-distance helioseismology (e.g., Duvall et al., 1993).

The correlation function of the fields recorded at two points is used as a virtual seismogram for which the source is acting at one point and the receiver at the second. For two signals of duration T, the correlation of the signal $u_1(t)$ at $\vec{r}_1$ and $u_2(t)$ at $\vec{r}_2$ is defined classically in the time domain as

$$C\left(\vec{r}_1, \vec{r}_2; t\right) = C_{1,2}(t) = \frac{1}{T}\int_0^T u_1(\tau)u_2(t+\tau)\mathrm{d}\tau \qquad [1]$$

or, equivalently, in the frequency domain as

$$C\left(\vec{r}_1, \vec{r}_2; \omega\right) = C_{1,2}(\omega) = u_1(\omega)u_2^*(\omega) \qquad [2]$$

The correlation function is widely used to measure the resemblance of two signals, and when these signals are similar enough, the time delay that separates them. The ambient noise signals recorded at distant stations are considered to be uncorrelated, as they result from variable interferences between numerous waves of different types emitted by different sources. The same argument holds for the scattered waves that comprise the coda of seismograms. Noise-correlation methods aim at extracting the slight coherent part of the signals that contains deterministic information on wave propagation between the two stations. Indeed, in a medium governed by a wave equation, the motion at two points cannot be fully independent. The extraction of the wave response between the two points is made possible by averaging the correlation over the positions of the sources of the signals. Note that, in the reasoning, the sources include the scatterers viewed as secondary sources.

1.12.3.1 The Time-Reversal Approach

A simple, heuristic approach is based on the analogy between a correlation and a time-reversal experiment (e.g., Derode et al., 2003a,b; Paul et al., 2005). While not completely rigorous in a general case, this analogy allows for an understanding of the physical processes behind the noise-correlation method. In a time-reversal experiment in the laboratory, signals from an active source are recorded, numerically reversed ($t \rightarrow -t$), and then reemitted in the medium (e.g., Fink, 1992). According to the time symmetry of the solutions of the wave equations, the waves propagate, and under certain conditions, they focus on the original source position. In a scalar case, the conditions in such an experiment are that the recording–reemission point distribution is sufficient to reconstruct the angular range of the original wave field. Typically, this is the case with a closed cavity that contains the source. When the re-emitted field is perfectly focused, the focal point can be considered as a virtual source. In seismology, there is no device that can emit a complex signal with sufficient energy. The approach to the construction of signals from virtual sources is completely passive. We consider the mathematical analogy between correlation and convolution by a time-reversed signal. Indeed, the cross-correlation of the signal produced by a source in S at receivers at A and B is formally equivalent to having a source at A producing waves that are recorded at S, time-reversed, and re-emitted from S, to be recorded at B (as written in the frequency domain in eqn [[2]]).

These operations are illustrated in Figure 1 with numerical simulations. For the sake of simplicity, we consider 2D scalar propagation in a weakly scattering medium (Paul et al., 2005).

The field produced by each of several sources S along a circle is computed at each point of the medium (Figure 1(a)). The signals are cross-correlated with the signal of a central reference point. The correlations are shown in Figure 1(b)–1(d) for correlation times −30, 0, and 30 s. At time $t = 0$, all the energy is focused on A, as if A were a source. A converging wave front for negative correlation times and a diverging wave front for positive correlation times are observed. These wave fronts correspond to the causal (positive times) and anticausal (negative time) parts of the Green's function between A and any point R in the medium. The nearly perfect reconstruction of the Green's function, similar to a perfect time-reversal mirror, is explained by the perfect distribution of the source around A and R. To illustrate a practical application, snapshots of ambient noise correlations produced with USArray data (Lin et al., 2009) are presented in Figure 1(e). The clearly diverging surface wave front suggests that the array is surrounded by distant noise sources.

1.12.3.2 Stationary Phase and End-Fire Lobes

Following the time-reversal analogy, it can be asked whether all the noise sources that surround the two receivers in the correlation process contribute in the same manner to the reconstruction of the Green's function. In the absence of scatterers that can redirect the field in all directions, the Green's function emerges from the correlations that contain noise sources where their acoustic path passes through one receiver to reach the other one.

An experimental demonstration of this process was performed from ocean data simultaneously recorded on two sonobuoys at a few hundred meters from each other in a shallow-water environment. Noise was generated over 16 min in the 100–300 Hz frequency interval using a ship, the track of which is represented in Figure 2(a). The two 16-min-long time-series are then cross-correlated using different time windows (Figure 2(b)–2(f)). When the correlation is performed on a 1-s-duration time series (Figure 2(b)), the ship track is clearly observed. If the length of the cross-correlated time series is increased to 5, 10, 20, and up to 30 s (Figure 2(b)–2(e), respectively), the signature of the ship track tends to disappear and the only signal left is obtained when the ship crosses the end-fire main lobes, which is defined as the directivity pattern of the time-domain cross-correlation between the two sensors (Figure 2(a)).

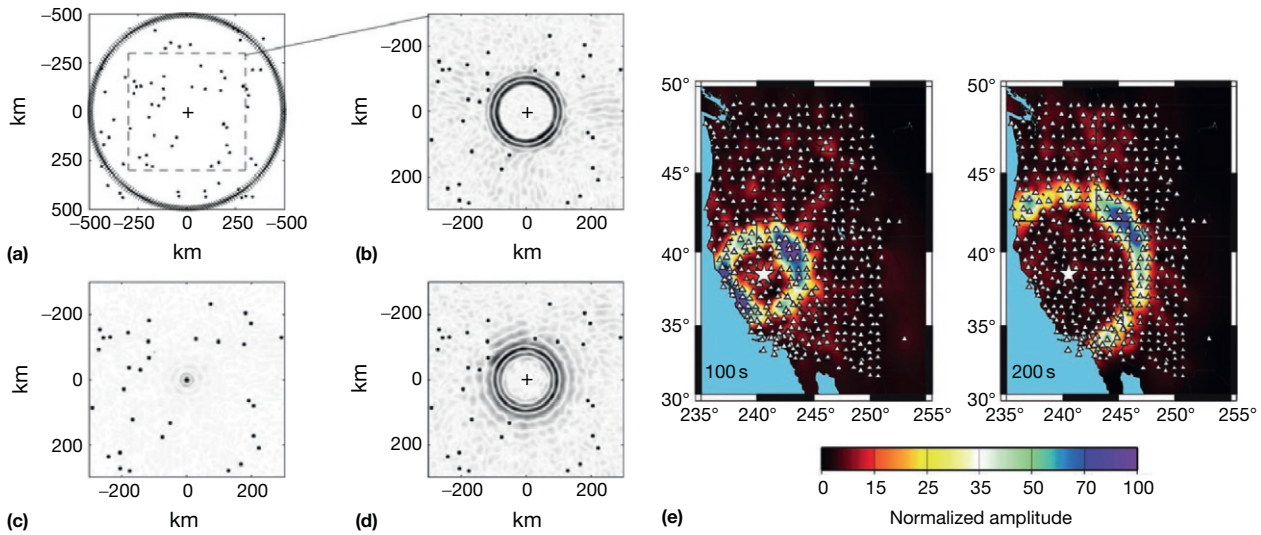

Figure 1 Numerical simulation of the reconstruction of the causal and anticausal parts of the Green's function from cross-correlations. (a) Configuration of the numerical experiment. One thousand sources S (×) surround the reference point A (+). Dots indicate the point scatterers. (b) Snapshot of the cross-correlation between the field at A and the field at location (x, y), after averaging over the sources S for the correlation time of 30 s. The weakly diffusive medium is characterized by the transport mean free path $l^* = 640$ km, which is greater than the distance between the points where the correlations are computed. A converging wave front is well defined and constitutes the anticausal part of the Green's function. (c) Snapshot for correlation time $t = 0$ s. The wave front is focused on A. (d) Snapshot for $t = 30$ s. The diverging wave front corresponds to the causal part of the Green's function. Parts (a)–(d) reproduced from Paul A, Campillo M, Margerin L, Larose E, and Derode A (2005) Empirical synthesis of time-asymmetrical Green function from the correlation of coda waves. *Journal of Geophysical Research* 110. http://dx.doi.org/10.1039/2004JB003521. (e) Snapshots of the actual noise correlation computed from a network in western United States showing the causal surface wave part of the Green's function. Reproduced from Lin FC, Ritzwoller MH, Snieder R (2009) Eikonal tomography: Surface wave tomography by phase front tracking across a regional broad-band seismic array. *Geophysical Journal International* 177: 1091–1110.

When coming from the end-fire lobe of the two receivers, the signal is produced by a noise source where its acoustic path that passes through one receiver naturally reaches the other receiver. The signals are then similar at the two receivers and contribute coherently to the correlation process with a unique delay time that corresponds to the travel time between the receivers. On the contrary, for a noise source outside the end-fire lobe, the ray paths that connect the source to each receiver do not superimpose. The sources out of the end-fire lobes do not contribute coherently to the correlation, as the correlated waveforms correspond to time delays that vary rapidly with the noise-source position.

Obviously, it is observed in Figure 2(b)–2(f) that the longer the correlation window, the higher the signal-to-noise ratio (SNR), because more acoustic sources participate coherently in the correlation function when the incoherent contribution averages out. Indeed, assuming that the speed of the ship was constant during the track, it generates a uniform density of sources over time. For long time windows, the SNR of the correlation process can be defined as the ratio of the number of coherent *versus* incoherent sources inside the recording time window.

In summary, the averaging of the correlation process over time magnifies the coherent *versus* incoherent contributions of the noise sources. Following the geometrical interpretation, the coherent *versus* incoherent ratio corresponds to the area enclosed by the end-fire beam to a non-end-fire beam.

Finally, note that the time-averaged correlation function in Figure 2(f) shows different bottom-reflection and surface-reflected paths that correspond to the arrival-time structure of the Green's function in a shallow-water environment.

Another way to understand the Green's function reconstruction is to separate the contribution that each noise source makes to the correlation process. This was made possible with actual data from a high-resolution survey performed by Petroleum Development Oman (PDO) in North Oman. During this active-seismic survey, a large set of 1600 vibrators were used in combination with 1600 receivers over a 1-km^2 area, to measure the 1600×1600 time-domain signals that constituted an exhaustive measurement of the transfer function of the half-space medium.

From this data set, we select a pair of receivers that are separated by a distance of $d = 158$ m, with a midpoint that coincides with the center of the ring in Figure 3(a). This ensures the same scattering regime for both of the receivers at a given time of the records. Integrating over a line surrounding the receiver pair is theoretically sufficient to get the Green's function, as in our case the medium is lossless. As shown in Figure 3(a), sources inside a ring were selected to increase the SNR when computing the cross-correlation. The azimuth is defined with respect to the receiver pair, denoted by θ, as the difference between the azimuth defined by one source and the receiver pair center and the receiver pair azimuth (Figure 3(c), insert).

The end-fire lobes of the receiver pairs are the areas located in the alignment of the receivers (one on each side). The end-fire lobe aperture depends on the ratio between the wavelength and the range between the receivers (Roux and Kupermann, 2004) and corresponds to the misalignment of the source with respect to the receiver pair. Sources located exclusively within the end-fire lobes induce time delays between the apparent travel time at the two receivers that are smaller than one-eighth of the central period associated to the source spectrum

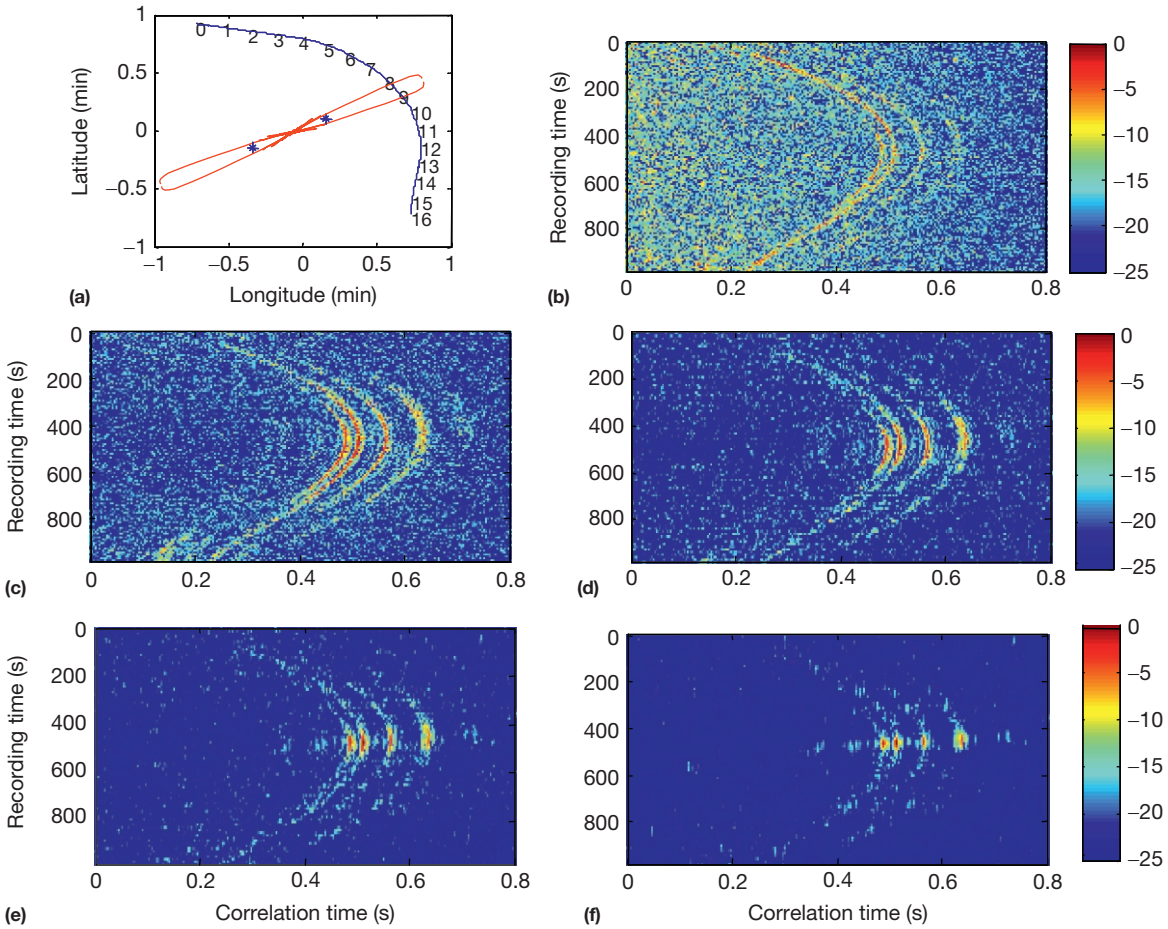

Figure 2 (a) Representation in latitude–longitude coordinates of a 16-min-long ship track (blue full line) with respect to the sonobuoy locations (blue *). The approximate distance between the sonobuoys is R, at ~650 m. The average ship speed was constant, at 4.8 m s^{-1}. The labels along the ship track correspond to each minute of the recording time window. The end-fire directivity pattern of the two sonobuoys is plotted in red. (b–f) Representations of the temporal evolution of the time-domain cross-correlation function between the two sonobuoys along the 16-min-long ship track. The *x*-axis and *y*-axis correspond to the time axis of the correlation function and the recording time, respectively. The duration of the time windows on which the cross-correlation was performed was (b) 1 s, (c) 5 s, (d) 10 s, (e) 20 s, and (f) 40 s. Each cross-correlation pattern is normalized relative to its maximum. The color scales are in dB. Reproduced from Roux P and Kupermann WA (2004) Extraction of coherent wavefronts from ocean ambient noise. *Journal of the Acoustical Society of America* 116(4): 1995–2003.

(Figure 2(a)). In other words, the end-fire lobes are areas in which the phase of the correlation function of direct waves is stationary with respect to azimuth θ.

Figure 3(c) shows that when considering direct arrivals, the cross-correlation function is highly dependent on the source azimuth when it is computed independently for each source. When stacking the contributions of all the sources (viz., all the azimuths), all the phases are averaged, and only the contributions of sources in the end-fire lobes, where the delays are stationary, do not vanish. This leads to a good estimate of the actual direct-wave component of the Green's function. The average cross-correlation and the actual response as recorded in the field are compared in Figure 3(d). Satisfactory reconstruction of the direct waves was achieved. Following Snieder (2004), the same approach was also proposed for the correlation of coda waves (Figure 3(b)) where the scatterers play the role of virtual sources surrounding the receiver pair (Gouédard et al., 2008a).

1.12.4 Mathematical Results

1.12.4.1 Homogeneous Body Approximation

The goal of this section is to investigate the following problem theoretically: can the Green's function between two points be retrieved by performing a cross-correlation of the ambient-noise field received on those two points?

For the sake of simplicity, we consider the scalar-wave problem for which the Green's function G is defined as the solution of the wave equation

$$\Delta G\left(\vec{x};t\right) - \frac{1}{c^2}\frac{\partial G\left(\vec{x};t\right)}{\partial t^2} = \delta\left(\vec{x}\right)\delta(t) \qquad [3]$$

1.12.4.1.1 The plane-wave representation in free space

From a theoretical point of view, earlier studies have investigated the problem of spatial correlation with noise fields or with wave fields obtained from a distribution of random

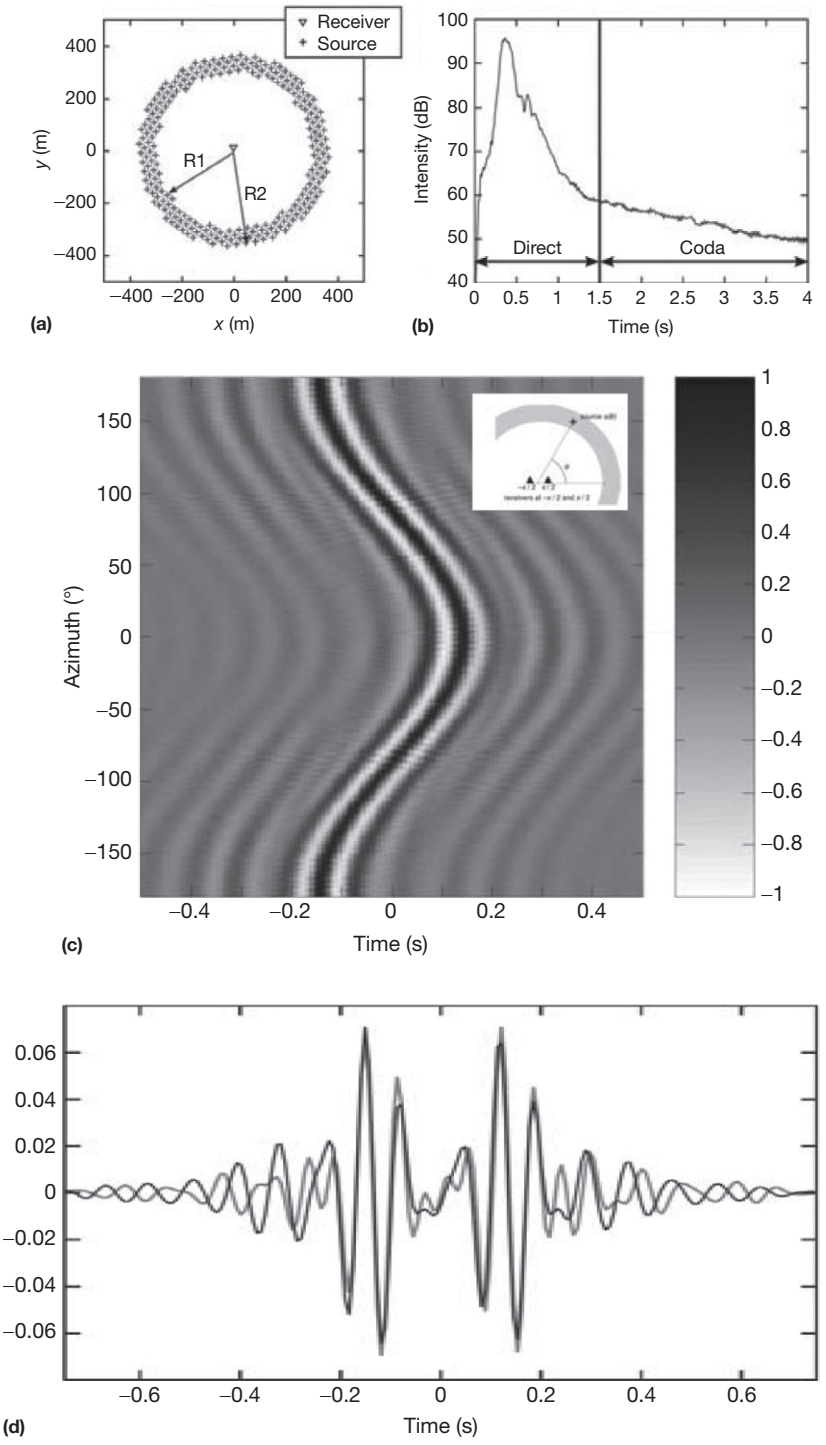

Figure 3 (a) Experimental geometry when considering sources that surround a receiver pair. The selection was for 240 sources located between two circles of radius $R_1 = 300$ m and $R_2 = 370$ m, which were centered at the middle of the receiver pair. (b) Average intensity of the raw traces with definition of the time windows corresponding to direct arrivals and to coda. (c) Cross-correlation functions obtained from each source and plotted as a function of azimuth θ (see definition on the insert). (d) Actual experimental Green's function and cross-correlation averaged over the sources (see panel (a)). Reproduced from Gouédard P, Roux P, Campillo M, and Verdel A (2008a) Convergence of the two-points correlation function toward the Green's function in the context of a prospecting dataset. *Geophysics* 73(6): V47–V53.

sources. For example, this problem was studied by Aki (1957) for surface waves. He considered the 2D case with scalar waves in a homogeneous medium from the perspective of isotropic illumination by plane waves.

The plane waves at angular frequency ω generated from sources at large distances and propagating in direction ψ are of the form

$$u\left(\vec{r}_1;\omega\right) = F(\omega)\exp\left(\mathrm{i}k\vec{r}_1\cdot\vec{n}\right) \qquad [4]$$

where $u(\vec{r}_1;\omega)$ is a displacement at position $\vec{r}_1$ of a Cartesian frame, and $k=\omega/c$ is the wave number for a plane wave incoming from the direction $\vec{n}=(\cos\psi,\sin\psi)$ with amplitude $F(\omega)$. Assuming an omnidirectional distribution of incident plane waves, the field correlation between two points $\vec{r}_1$ and $\vec{r}_2$ reduces to the well-known form of a Bessel function:

$$\left\langle u\left(\vec{r}_1;\omega\right)u^*\left(\vec{r}_2;\omega\right)\right\rangle = |F(\omega)|^2 J_0\left(k\left|\vec{r}_1-\vec{r}_2\right|\right) \qquad [5]$$

where $J_0(k|\vec{r}_1-\vec{r}_2|)$ is the Bessel function of the first kind and order 0. This is the essence of the spatial correlation methods proposed originally by Aki (1957), and which have been extensively used to study the structure of shallow structures.

From there, we can identify J_0 as a constituent of the 2D scalar Green's function:

$$\begin{aligned} G\left(\vec{r}_1,\vec{r}_2;\omega\right) &= \frac{1}{4\mathrm{i}}H_0^{(1)}\left(k\left|\vec{r}_1-\vec{r}_2\right|\right) \\ &= \frac{1}{4\mathrm{i}}\left(J_0\left(k\left|\vec{r}_1-\vec{r}_2\right|\right)+\mathrm{i}Y_0\left(k\left|\vec{r}_1-\vec{r}_2\right|\right)\right) \end{aligned} \qquad [6]$$

where Y_0 and $H_0^{(1)}$ are the Neumann and Hankel functions of zero order.

We finally obtain

$$\left\langle u\left(\vec{r}_1;\omega\right)u^*\left(\vec{r}_2;\omega\right)\right\rangle = -4|F(\omega)|^2\,\mathrm{Im}\left[G\left(\vec{r}_1,\vec{r}_2;\omega\right)\right] \qquad [7]$$

As shown in eqn [7], the correlation theorem links the average correlation function (left term) to the imaginary part of the Green's function. The time domain signal associated with Im(G) by Fourier transform is the causal Green's function plus its even anticausal time-symmetrical counterpart, as shown in the next paragraph.

The generalization to the 3D free-space medium with a spatially uniform noise-source distribution is straightforward, as the field at each receiver can be decomposed as a superposition of uncorrelated plane waves from various directions. It has been established that the normalized cross-spectral density $C_{1,2}(\omega)$ at frequency ω between two receivers 1 and 2 separated by a distance $r=|\vec{r}_1-\vec{r}_2|$ is

$$C_{1,2}(\omega) = \frac{\sin(kr)}{kr} \qquad [8]$$

In the time domain, the normalized correlation function is

$$C_{1,2}(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} C_{1,2}(\omega)\exp(\mathrm{i}\omega t)\,\mathrm{d}\omega \qquad [9]$$

which can be written as

$$\begin{aligned} C_{1,2}(t) = &\frac{1}{4\pi}\int_{-\infty}^{\infty}\frac{\exp[\mathrm{i}\omega(t+r/c)]}{\mathrm{i}kr}\,\mathrm{d}\omega \\ &-\frac{1}{4\pi}\int_{-\infty}^{\infty}\frac{\exp[\mathrm{i}\omega(t-r/c)]}{\mathrm{i}kr}\,\mathrm{d}\omega \end{aligned} \qquad [10]$$

The time derivative of the correlation function, then, is

$$\frac{\mathrm{d}}{\mathrm{d}t}C_{1,2}(t) = \frac{1}{4\pi r/c}[\delta(t+r/c)-\delta(t-r/c)] \qquad [11]$$

The two terms in eqn [11] correspond to the backward and forward Green's function between the receivers, which demonstrates the connection between the correlation function and the Green's function.

Note that Nakahara (2006) studied in detail the relations between the spatial correlation functions and the Green's function, in 1D, 2D, and 3D cases. He emphasized the dimensional character of these relations, essentially as a Hilbert transform in 2D and a differentiation in 3D.

However, the drawback of the elegant result in eqn [11] is to start from a *normalized* correlation function, the normalization being required because the overall spatial contribution from noise sources in a lossless infinite medium is infinite. Experimentally though, ambient noise signals are always finite, as is the noise correlation function. The contradiction arises because the theory is developed in lossless environments while experiments are always performed in the presence of attenuation. Thus, normalization acts as a subterfuge for avoiding the inclusion of the required attenuation in the theory.

1.12.4.1.2 Case of a homogeneous distribution of noise sources

The goal of this section is to show how the result in eqn [11] can be derived rigorously without the need for normalization when attenuation is present in the medium.

To be as general as possible, we deal here with two receivers that are simultaneously recording ambient noise in a 3D homogeneous medium with an omnidirectional and uniform distribution of noise sources. The incident field on the two receivers comes from a homogeneous spatial–temporal distribution of uncorrelated broadband noise sources. Volume attenuation is included in the medium with an attenuation parameter κ.

The Green's function between points A (in $\vec{r}_1$) and B (in $\vec{r}_2$) is then defined as follows:

$$G\left(\vec{r}_1,\vec{r}_2;t\right) = \frac{1}{2\pi}\int_{-\infty}^{+\infty}\mathrm{d}\omega\,\frac{1}{4\pi\left|\vec{r}_2-\vec{r}_1\right|}\exp\left[\mathrm{i}\omega\left(t-\frac{\left|\vec{r}_2-\vec{r}_1\right|}{c}\right)\right]\exp\left(-\kappa\left|\vec{r}_2-\vec{r}_1\right|\right) \qquad [12]$$

Assuming a random spatial–temporal distribution of noise source amplitudes $S(\vec{r}_s, t_s)$, the total field received at A is

$$P\left(\vec{r}_1;t\right) = \int_{-\infty}^{\infty}\int_{-\infty}^{t} \mathrm{d}\vec{x}\ \mathrm{d}t_x S\left(\vec{x},t_x\right) G\left(\vec{r}_1,\ \vec{x};t-t_x\right) \qquad [13]$$

Here, the causality requires that the noise sources in $(\vec{x};t_x)$ that contribute to the pressure field at A at a given time t satisfy the condition $t = t_x + \frac{\left|\vec{r}_1-\vec{x}\right|}{c}$. Then the cross-correlation of the two signals recorded at A and B is defined as in eqn [1]:

$$C\left(\vec{r}_1,\vec{r}_2;t\right) = C_{1,2}(t) = \frac{1}{T}\int_0^T P\left(\vec{r}_1;\tau\right) P\left(\vec{r}_2;t+\tau\right)\mathrm{d}\tau \qquad [14]$$

$C_{1,2}(t)$ corresponds to one realization of the ambient noise cross-correlation function. To evaluate the average noise correlation function $\langle C_{1,2}(t)\rangle$ over an ensemble of realization, we use the idea that noise sources are spatially and temporally uncorrelated:

$$\left\langle S\left(\vec{x},t_x\right)S\left(\vec{x}',t_{x'}\right)\right\rangle = Q^2\delta\left(t_x-t_{x'}\right)\delta\left(\vec{x}-\vec{x}'\right) \qquad [15]$$

where the notation $\langle X\rangle$ corresponds to the ensemble average of X, and Q^2 is the acoustic power of the noise sources and is taken as constant over time and space. Then it follows that

$$\langle C_{1,2}(t)\rangle = \frac{Q^2}{64T\pi^4}\int_0^T\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty}\frac{n(\tau)\mathrm{d}\tau\,\mathrm{d}\vec{x}\ \ \mathrm{d}\omega}{\left|\vec{r}_2-\vec{x}\right|\left|\vec{r}_1-\vec{x}\right|}$$
$$\exp\left[\mathrm{i}\omega\left(t+\frac{\left|\vec{r}_1-\vec{x}\right|}{c}-\frac{\left|\vec{r}_2-\vec{x}\right|}{c}\right)\right]$$
$$\exp\left[-\kappa\left(\left|\vec{r}_1-\vec{x}\right|+\left|\vec{r}_2-\vec{x}\right|\right)\right] \qquad [16]$$

Note that, as written in eqn [14], n is the number of sources by unit time, and τ corresponds to the running time of the signals received at A and B. The cross-correlation function $\langle C_{1,2}(t)\rangle$ is a comparison between these two signals, meaning that $\langle C_{1,2}(t)\rangle$ will extract the relative propagation times between the noise source in $\vec{x}$, and the receivers in $\vec{r}_1$ and $\vec{r}_2$. As a consequence, the integration over τ corresponds to just an accumulation of noise sources over time. In a practical experimental case, the pressure fields at A and B have first to be recorded over a finite interval time T before the cross-correlation is performed.

Assuming that the random noise sources have a constant creation rate $n(\tau)=N$, the integral over τ is changed into the product $T\times N$. Finally, using this approach, eqn [9] becomes

$$\langle C_{1,2}(t)\rangle = \frac{Q^2N}{64\pi^4}\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty}\frac{\mathrm{d}\vec{x}\ \mathrm{d}\omega}{\left|\vec{r}_2-\vec{x}\right|\left|\vec{r}_1-\vec{x}\right|}$$
$$\exp\left[\mathrm{i}\omega\left(t+\frac{\left|\vec{r}_1-\vec{x}\right|}{c}-\frac{\left|\vec{r}_2-\vec{x}\right|}{c}\right)\right]$$
$$\exp\left[-\kappa\left(\left|\vec{r}_1-\vec{x}\right|+\left|\vec{r}_2-\vec{x}\right|\right)\right] \qquad [17]$$

Equation [16] shows that the noise correlation function in free space reduces to the calculation of a spatial integral over the noise–source locations. In the following paragraph, we show that a geometrical argument allows us to obtain an analytical solution for $\langle C_{1,2}(t)\rangle$. We first define a Cartesian coordinate system for the 3D space in which A is $(a,0,0)$, and B is $(-a,0,0)$. The argument of the time-dependent exponential in eqn [17] gives a contribution to the correlation function at time t if $\vec{x}$ is such that $|\vec{r}_2-\vec{x}|-|\vec{r}_1-\vec{x}|=ct$.

For a time t satisfying the condition $-2a\le ct\le 2a$, the noise sources must lie on a hyperboloid (Figure 4) that will contribute to $\langle C_{1,2}(t)\rangle$ at a given time t. This implies that $\langle C_{1,2}(t)\rangle = 0$ for t outside the interval $[-2a/c,\ 2a/c]$. Similarly, the ellipse in Figure 4 is made of the noise sources $\vec{r}_s$ such that $|\vec{r}_2-\vec{x}|+|\vec{r}_1-\vec{x}|=$constant, that is, sources that contribute to the correlation function with the same attenuation.

Note that these conical shapes are invariant by rotation around the axis of the two receivers (Figure 4, x-axis). This means that in 3D, the hyperbola and the ellipse turn out to be a hyperboloid and an ellipsoid where the symmetry axis is the lines between the two receivers. As can be seen in Figure 2, every noise source in space belongs to a unique hyperbola.

Using a change of variable from the Cartesian coordinates to the Prolate spheroidal coordinates, it follows that

$$\langle C_{1,2}(t)\rangle = \frac{Q^2Nc}{64\pi\kappa}\int_{\infty}^{+\infty}\mathrm{d}\omega\,\frac{1}{\mathrm{i}\omega}\left\{\exp\left[\mathrm{i}\omega\left(t+\frac{2a}{c}\right)\right]\right.$$
$$\left.-\exp\left[\mathrm{i}\omega\left(t-\frac{2a}{c}\right)\right]\right\}\frac{\exp\left(-2a\kappa\right)}{2a} \qquad [18]$$

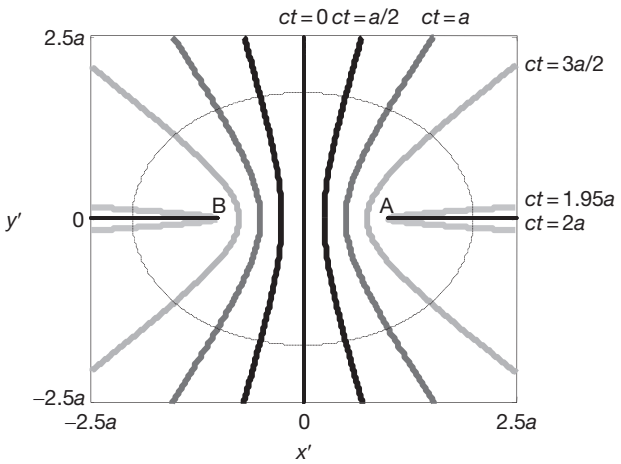

Figure 4 Representation in the x–y plane of the hyperbola that contributes to a given time t in the noise-correlation function. On each hyperbola, the noise sources satisfy $|\vec{r}_2-\vec{x}|-|\vec{r}_1-\vec{x}|=ct$. For example, the horizontal axis corresponds to $ct=0$. The vertical axis corresponds to $ct=2a$ for $x'\ge a$, and $ct=-2a$ for $x'\le -a$. The ellipse (dashed line) represents the noise sources for which $|\vec{r}_2-\vec{x}|-|\vec{r}_1-\vec{x}|=ct$, for $ct=4a$. The receivers A and B are at $(a,0)$ and $(-a,0)$. From Roux P, Sabra KG, Kuperman WA, and Roux A (2005b) Ambient noise cross correlation in free space: Theoretical approach. *Journal of the Acoustical Society of America* 117: 79–84.

In the case of a medium with attenuation, the time derivative of the correlation function gives

$$\frac{\mathrm{d}}{\mathrm{d}t}\langle C_{1,2}(t)\rangle = \frac{Q^2 N c}{64\pi\kappa}\left\{\int_{-\infty}^{+\infty}\mathrm{d}\omega\frac{1}{2a}\exp\left[\mathrm{i}\omega\left(t+\frac{2a}{c}\right)\right]\exp\left(-2a\kappa\right) - \int_{-\infty}^{+\infty}\mathrm{d}\omega\frac{1}{2a}\exp\left[\mathrm{i}\omega\left(t-\frac{2a}{c}\right)\right]\exp\left(-2a\kappa\right)\right\} \quad [19]$$

The physical interpretation of eqn [19] is

$$\frac{\mathrm{d}}{\mathrm{d}t}\langle C_{1,2}(t)\rangle = Q^2 N\frac{c}{2\kappa}\left[G\left(\vec{r}_1,\vec{r}_2;t\right) - G\left(\vec{r}_1,r_2;-t\right)\right] \quad [20]$$

The amplitude term in the factor of the causal and anticausal Green's function is made up of two contributions: (1) Q^2N, which corresponds to the noise power during the recording time window T; and (2) the other factor $\frac{c}{2\kappa}$, which is directly related to the attenuation introduced in the Green's function (eqn [12]). In Section 1.12.4.3, we will see the importance of this attenuation parameter in the more general formulation of the Ward Identity. Indeed, the introduction of a small attenuation in the medium makes the correlation function converge on the noise–source spatial distribution without any constraint. Finally, the derivative of the ambient noise correlation function generates the causal and anticausal (or time-reversed) Green's functions between the two points at which the noise has been recorded.

1.12.4.2 The Case of a Single Scatterer

The correlation theorem is generalized to the case where there is one punctual and isotropic weak scatterer in the propagation medium. The Green's function is now made up of both the direct path between the source and the receiver and the scattering contribution from the scatterer. Before generalization to a more complex heterogeneous medium (Section 1.12.4.3), the goal of this paragraph is to show how the two-point correlation function provides the two contributions of the Green's function.

The mathematical demonstration was proposed by Sato et al. (2012), who considered the scattering contribution in the first Born approximation. The Green's function $G^0\left(\vec{r}_1,\vec{x};\omega\right) = G^0_{1x}$ of the free-space medium that is the solution of the Helmoltz equation between one source in $\vec{r}_1$ and one receiver in $\vec{x}$, as

$$\Delta G^0_{1x} + (k+\mathrm{i}\kappa)^2 G^0_{1x} = \delta\left(\vec{r}_1 - \vec{x}\right) \quad [21]$$

is transformed into $G(\vec{r}_1,\vec{x};\omega) = G_{1x}$, such that

$$\Delta G_{1x} + (k+\mathrm{i}\kappa)^2 G_{1x} + V_0\delta\left(\vec{x}-\vec{y}\right)G_{1x} = \delta\left(\vec{r}_1-\vec{x}\right) \quad [22]$$

where $\vec{y}$ is the position of the scatterer, and V_0 is the scattering coefficient.

Assuming $G_{1x} = G^0_{1x} + G^s_{1x}$, we have in the first Born approximation ($|G^s_{1x}| \ll |G^0_{1x}|$) for the scattering contribution

$$\Delta G^s_{1x} + (k+\mathrm{i}\kappa)^2 G^s_{1x} = -V_0\delta\left(\vec{x}-\vec{y}\right)G^0_{1x} \quad [23]$$

from which we obtain

$$G_{1x} = -\frac{1}{4\pi r_{1x}}\exp\left[(\mathrm{i}k-\kappa)r_{1x}\right] + V_0\frac{\exp\left[(\mathrm{i}k-\kappa)r_{1y}\right]}{4\pi r_{1y}} \times \frac{\exp\left[(\mathrm{i}k-\kappa)r_{xy}\right]}{4\pi r_{xy}} \quad [24]$$

where $r_{1x} = |\vec{r}_1 - \vec{r}_x|$ and $r_{xy} = |\vec{r}_x - \vec{r}_y|$.

The correlation function is defined in the frequency domain as

$$C_{1,2}(\omega) = \int_{-\infty}^{+\infty} G^*_{1x}(\omega)G_{2x}(\omega)\,\mathrm{d}\vec{x} \quad [25]$$

with noise sources that spread to infinity. Replacing G_{1x} and G_{2x} by their expression in eqn [24], it follows from the Born approximation that

$$C_{1,2}(\omega) = \int_{-\infty}^{+\infty}\left[G^0_{1x}(\omega)^* G^0_{2x}(\omega) + G^s_{1x}(\omega)^* G^0_{2x}(\omega) + G^0_{1x}(\omega)^* G^s_{2x}(\omega)\right]d\vec{x} \quad [26]$$

from which we obtain

$$\begin{aligned} C_{1,2}(\omega) = &\int_{-\infty}^{+\infty}\frac{\exp\left[(-\mathrm{i}k-\kappa)r_{1x}\right]}{4\pi r_{1x}}\frac{\exp\left[(\mathrm{i}k-\kappa)r_{2x}\right]}{4\pi r_{2x}}\mathrm{d}\vec{x} \\ &-V_0\frac{\exp\left[(-\mathrm{i}k-\kappa)r_{1y}\right]}{4\pi r_{1y}} \\ &\int_{-\infty}^{+\infty}\frac{\exp\left[(-\mathrm{i}k-\kappa)r_{xy}\right]}{4\pi r_{xy}}\frac{\exp\left[(\mathrm{i}k-\kappa)r_{2x}\right]}{4\pi r_{2x}}\mathrm{d}\vec{x} \\ &-V_0\frac{\exp\left[(\mathrm{i}k-\kappa)r_{2y}\right]}{4\pi r_{2y}} \\ &\int_{-\infty}^{+\infty}\frac{\exp\left[(-\mathrm{i}k-\kappa)r_{1x}\right]}{4\pi r_{1x}}\frac{\exp\left[(\mathrm{i}k-\kappa)r_{xy}\right]}{4\pi r_{xy}}\mathrm{d}\vec{x} \end{aligned} \quad [27]$$

Using the change of variable and the spatial integration performed in Section 1.12.4.1 (from eqn [17] to eqn [18]), we have

$$\begin{aligned} C_{1,2}(\omega) = &\frac{1}{2k\kappa}\exp\left(-\kappa r_{12}\right)\frac{\sin\left(kr_{12}\right)}{4\pi r_{12}} \\ &-V_0\frac{\exp\left[(-\mathrm{i}k-\kappa)r_{1y}\right]}{4\pi r_{1y}} \\ &\frac{1}{2k\kappa}\exp\left(-\kappa r_{2y}\right)\frac{\sin\left(kr_{2y}\right)}{4\pi r_{2y}} \\ &-V_0\frac{\exp\left[(\mathrm{i}k-\kappa)r_{2y}\right]}{4\pi r_{2y}} \\ &\frac{1}{2k\kappa}\exp\left(-\kappa r_{1y}\right)\frac{\sin\left(kr_{1y}\right)}{4\pi r_{1y}} \end{aligned} \quad [28]$$

which can be simplified as

$$C_{1,2}(\omega) = \frac{1}{2k\kappa}\exp\left(-\kappa r_{12}\right) = \frac{\sin\left(kr_{12}\right)}{4\pi r_{12}} - V_0\frac{1}{2k\kappa}\exp\left[-\kappa\left(r_{1y}+r_{2y}\right)\right]\frac{\sin\left[k\left(r_{1y}+r_{2y}\right)\right]}{4\pi r_{1y}4\pi r_{2y}} \quad [29]$$

We recognize in eqn [29] the part of the Green's function that is associated to the direct path between the receiver and the

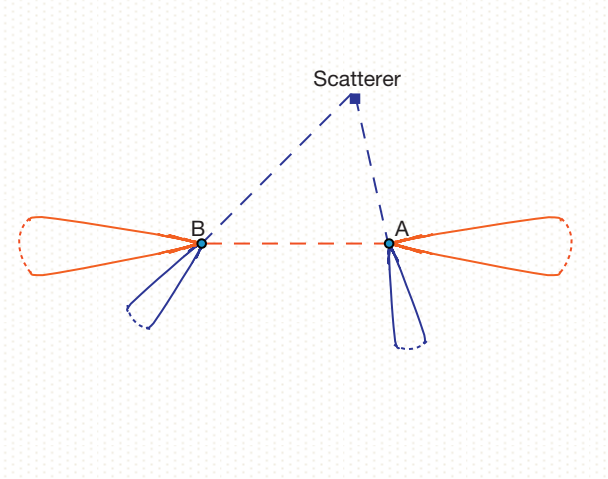

Figure 5 Schematic representation of the end-fire lobes (red) associated to the coherent contribution of noise sources (gray dots in the background) to the correlation function between two receivers at A and B. The part of the Green's function associated to the scatterer (blue square) is reconstructed from noise sources located in different beams (blue). For the sake of clarity, the dashed lines (red and blue) represent the direct and scattered ray paths, respectively.

contribution of the scatterer. From the integral in eqn [26], it is interesting to highlight the location of the noise sources that contribute to the reconstruction of the direct path or the scatterer contribution (Figure 5). In addition to the end-fire lobe that defines the angle interval in which noise sources coherently contribute to the direct path of the Green's function (Figure 5, red), there are new angle intervals associated to the coherent contribution of the scattered field (Figure 5, blue). As the path length of the scattered ray is longer than the A-to-B direct path, the width of this beam is smaller than the end-fire lobe.

Taking into account the Green's function formulation in eqn [24], we finally have

$$C_{1,2}(\omega) = \frac{c}{2i\omega\kappa}\mathrm{Im}[G_{12}(\omega)] \qquad [30]$$

Recognizing the time-derivative as the $i\omega$ term at the denominator in eqn [30], it follows that the correlation theorem is still valid for a medium with one local heterogeneity. Note that an extension of the plane-wave approach has also been performed in the presence of a scatterer (Sànchez-Sesma et al., 2006).

Following the same mathematical approach as in eqns [23]–[29], Sato et al. (2012) extended this result to a set of scatterers in the Born approximation. Finally, Margerin and Sato (2011) went a step further, showing that all of the scattering orders in the Dyson's equation (including multiple scattering) can be taken into account in the correlation function for the same result as in eqn [30].

1.12.4.3 Arbitrary Heterogeneous Medium

We now generalize the correlation theorem to the case of scalar waves propagating in any heterogeneous medium. This approach was first developed by Weaver and Lobkis (2004) and then by Snieder (2007). It indicates the role of attenuation in the connection between the correlation function and the Green's function.

We start from the Helmholtz equation that defines the Green's function $G_{1x}=G(\vec{r}_1,\vec{x};\omega)$ for scalar waves in a heterogeneous medium at frequency ω:

$$\Delta G_{1x} + V\left(\vec{x}\right)G_{1x} + (k+i\kappa)^2 G_{1x} = \delta\left(\vec{x}-\vec{r}_1\right) \qquad [31]$$

where the potential $V(\vec{x})$ describes the scattering contribution to the wavefield that is assumed to be finite in space, meaning that it does not extend to infinity.

Using two points in $\vec{r}_1$ and $\vec{r}_2$, we define the flux of the Poynting vector through a closed surface S located far away from any medium heterogeneity as

$$I = \oint_S \left[G_{1x}\,\vec{\nabla}\,(G^*_{2x}) - \vec{\nabla}\,(G_{2x})G^*_{1x}\right]\vec{\mathrm{d}S} \qquad [32]$$

Using the divergence theorem, we can transform this flux integral into a volume integral U:

$$I = \int_U \vec{\nabla}\left[G_{1x}\,\vec{\nabla}\,(G^*_{2x}) - \vec{\nabla}\,(G_{1x})G^*_{2x}\right]\mathrm{d}V \qquad [33]$$

This can be simplified to

$$I = \int_U (G_{1x}\Delta G^*_{2x} - \Delta G_{1x}G^*_{2x})\mathrm{d}V \qquad [34]$$

From eqn [31], we have

$$\Delta G^*_{2x} = \delta\left(\vec{x}-\vec{r}_2\right) - V\left(\vec{x}\right)G^*_{2x} - (k-i\kappa)^2 G^*_{2x} \qquad [35]$$

$$\Delta G_{1x} = \delta\left(\vec{x}-\vec{r}_1\right) - V\left(\vec{x}\right)G_{1x} - (k+i\kappa)^2 G_{1x} \qquad [36]$$

which assumes that the potential $V(\vec{x})$ is real. Physically speaking, this means that there is no vortex or flow in the medium that would break the spatial reciprocity theorem.

Combining eqns [35] and [36] with eqn [34], it follows that

$$I = G_{12} - G^*_{21} - \frac{4i\omega\kappa}{c}\int_U G_{1x}G^*_{2x}\mathrm{d}V \qquad [37]$$

Finally, using eqns [32] and [37], and taking into account that $G_{12}=G_{21}$, because of the reciprocity theorem, it can be concluded that

$$G_{12} - G^*_{12} = \frac{4i\omega\kappa}{c}\int_V G_{1x}G^*_{2x}\mathrm{d}V + \oint_S \left[G_{1x}\,\vec{\nabla}\,(G^*_{2x}) - \vec{\nabla}\,(G_{1x})G^*_{2x}\right]\vec{\mathrm{d}S} \qquad [38]$$

In eqn [38], the left-hand side corresponds to the causal and anticausal Green's function. Using an equivalent formulation (see Section 1.12.4.3.3) of the representation theorem, Snieder (2007) detailed the different contributions of the volume and surface integrals in a simple configuration. For the sake of simplicity, we propose to separately examine the volume and surface integrals in the two following cases.

1.12.4.3.1 If the attenuation parameter $\kappa \neq 0$

In the case where the attenuation parameter $\kappa \neq 0$, we make the choice to extend the volume U to infinity. This means that the volume integral over the 'noise sources' x spreads over infinity. The product $G_{1x}G^*_{2x}$ corresponds to the correlation

between the field received in $\vec{r}_1$ and $\vec{r}_2$ from a source in $\vec{x}$. Far from the medium heterogeneities, the Green's function decreases as

$$|G_{1x}| \sim \frac{1}{4\pi\left|\vec{x}-\vec{r}_1\right|}\exp\left(-\kappa\left|\vec{x}-\vec{r}_1\right|\right) \quad [39]$$

Then, we have in the far field, with $|\vec{x}| \gg |\vec{r}_1|, |\vec{r}_2|$

$$\left|G_{1x}\,\vec{\nabla}\,(G^*_{2x})\right| \sim \left|\vec{\nabla}\,(G_{1x})G^*_{2x}\right| \sim \frac{k^2}{16\pi^2\left|\vec{x}-\vec{r}_1\right|\left|\vec{x}-\vec{r}_2\right|}$$
$$\exp\left[-\kappa\left(\left|\vec{x}-\vec{r}_1\right|+\left|\vec{x}-\vec{r}_2\right|\right)\right] \quad [40]$$

such that $\oint_S\left[G_{1x}\,\vec{\nabla}\,(G^*_{2x}) - \vec{\nabla}\,(G_{1x})G^*_{2x}\right]\vec{\mathrm{d}S} \to 0$ even when the surface S expands to infinity, because of the exponential decrease caused by attenuation.

We then obtain

$$G_{12} - G^*_{12} = \frac{4\mathrm{i}\omega\kappa}{c}\int_U G_{1x}G^*_{2x}\mathrm{d}V \quad [41]$$

which has sometimes been defined as the Ward Identity in the recent literature.

Equation [41] is the generalization of eqns [20] and [30] to any heterogeneous medium in the presence of attenuation. As in eqn [30], note that the $\mathrm{i}\omega$ term on the right-hand side corresponds to the time-derivative of the correlation function. As shown in the previous equations, the attenuation parameter κ is a key parameter in the Ward Identity. Physically speaking, the attenuation manages to balance the energy flux in the system. Another interpretation of the attenuation is related to the thermodynamic equilibrium as defined through the fluctuation-dissipation theorem.

1.12.4.3.2 If the attenuation parameter $\kappa = 0$

In the case where the attenuation parameter $\kappa = 0$, eqn [38] is simplified into

$$G_{12} - G^*_{12} = \oint_S\left[G_{1x}\,\vec{\nabla}\,(G^*_{2x}) - \vec{\nabla}\,(G_{1x})G^*_{2x}\right]\vec{\mathrm{d}S} \quad [42]$$

In eqn [42], the sources are present only on the closed surface S, and no source is present in the volume. If the surface is taken in the far field of the medium heterogeneities, for every point x on the surface S, we have

$$G_{1x} \sim \frac{1}{4\pi\left|\vec{x}-\vec{r}_1\right|}\exp\left(-ik\left|\vec{x}-\vec{r}_1\right|\right) \text{ and}$$
$$\vec{\nabla}\,(G_{1x}) \sim \mathrm{i}\vec{k}G_{1x} \quad [43]$$

from which it follows that

$$G_{12} - G^*_{12} = -2i\frac{\omega}{c}\oint_S G_{1x}G^*_{2x}\mathrm{d}S \quad [44]$$

where the right-hand side corresponds to the correlation function calculated for sources located on the surface S. As before, the $\mathrm{i}\omega$ term refers to the time-derivative of the correlation function.

The last formulation of the correlation theorem is appealing for geophysicists who usually deal with noise sources at Earth's surface. However, according to eqn [44], the surface must surround the receiving points in $\vec{r}_1$ and $\vec{r}_2$, which never happens in practice. Note also that the approximation $\kappa = 0$ is not valid in most practical cases.

1.12.4.3.3 Another formulation of the correlation theorem

In the literature on ambient noise correlation, eqn [44] is classically defined as one formulation of the representation theorem, and a different mathematical expression is sometimes used (Godin, 2007; Wapenaar, 2004; Wapenaar and Fokkema, 2006):

$$\tilde{G}_{12} + \tilde{G}^*_{12} = \frac{2}{c}\oint_S \tilde{G}_{1x}\tilde{G}^*_{2x}\mathrm{d}S \quad [45]$$

Compared to eqn [44], this other formulation of eqn [45] connects the summation of the causal and anticausal Green's function to the correlation function without the time derivative. It is important to understand that the two expressions in eqns [44] and [45] are equivalent. Indeed, eqn [45] is obtained from a different definition of the Green's function (see eqn [31] for comparison):

$$\Delta\tilde{G}_{1x} + V\left(\vec{x}\right)\tilde{G}_{1x} + (k+\mathrm{i}\kappa)^2\tilde{G}_{1x} = \mathrm{i}\omega\delta\left(\vec{x}-\vec{a}\right) \quad [46]$$

this differs only in the source term on the right-hand side, which corresponds to a 'mass injection' in eqn [46] when the Green's function definition in eqn [31] refers to a 'momentum injection.'

Finally, some authors have dealt with the case of a complex potential $V(\vec{x})$, which would correspond, for example, to the presence of a vorticity field or a flow that breaks the condition of spatial reciprocity in the propagation medium. It appears then that the correlation function is no longer symmetric in time. The travel time associated to the causal part can then be different from the travel time of the anticausal part, as the Green's function from one receiver to the other is not equivalent to the Green's function along the reverse path (Wapenaar, 2006).

Note also that Colin de Verdière (2009, 2011) proposed a very general and quite mathematical approach where the wave propagator is simply defined as a self-adjoint differential operator. Including attenuation and taking into account any type of scattering in the wave equation for a homogeneous noise distribution, he retrieved the same connection between the correlation function and the causal/anticausal Green's function (eqns [20] and [41]).

1.12.4.4 Modal Approach in Finite Bodies

Up to this point, we have presented the formulation of the correlation theorem in open homogeneous or heterogeneous media. However, the first theoretical and experimental demonstration of the convergence of the correlation function toward the Green's function was performed in finite bodies in which the wave propagation is described from a modal approach (Weaver and Lobkis, 2001).

For the sake of simplicity, we deal with a 1D finite body, in which the Green's function can be written as an expansion in terms of the normal modes $U_n(x)$:

$$G(x_1,x_2;t)=c^2\sum_n U_n(x_1)U_n(x_2)\frac{\sin(\omega_n t)}{\omega_n}\Theta(t) \qquad [47]$$

where ω_n corresponds to the eigenfrequency of mode n and $\Theta(t)$ is the Heaviside function that is necessary to respect the causality of the Green's function.

When uncorrelated noise sources are uniformly distributed in the volume V of the finite body, the correlation function between two receivers at x_1 and x_2 can be written as

$$C_{1,2}(t)=\frac{1}{T}\int_0^T \mathrm{d}\tau\int_V \mathrm{d}x\,G(x_1,x;\tau)G(x_2,x;t+\tau) \qquad [48]$$

From eqn [47], it follows that

$$C_{1,2}(t)=\frac{c^4}{T}\int_0^T \mathrm{d}\tau\int_V \mathrm{d}x\sum_m\sum_n U_n(x_1)U_n(x)U_m(x_2)U_m(x)\,\frac{\sin(\omega_n\tau)}{\omega_n}\,\frac{\sin[\omega_m(t+\tau)]}{\omega_m} \qquad [49]$$

Using the orthonormality relation between modes

$$\int_0^L \mathrm{d}x\,U_n(x)U_m(x)=\delta_{nm} \qquad [50]$$

we have

$$C_{1,2}(t)=\frac{c^4}{T}\sum_n\frac{1}{\omega_n^2}U_n(x_1)U_n(x_2)\int_0^T \sin(\omega_n\tau)\sin[\omega_n(t+\tau)]\mathrm{d}\tau \qquad [51]$$

When the recording window T is long compared to the largest period of the excited modes ($T\gg 1/\omega_n,\ \forall n$), it follows that

$$C_{1,2}(t)=\frac{c^4}{2}\sum_n U_n(x_1)U_n(x_2)\frac{\cos(\omega_n t)}{\omega_n^2} \qquad [52]$$

and then,

$$\frac{\mathrm{d}}{\mathrm{d}t}C_{1,2}(t)=-\frac{c^4}{2}\sum_n U_n(x_1)U_n(x_2)\frac{\sin(\omega_n t)}{\omega_n}=-\frac{c^2}{4}[G(x_1,x_2;t)-G(x_1,x_2;-t)] \qquad [53]$$

As expected, the physics of the correlation theorem also applies to the modal formulation. Besides the thermal diffuse-noise experiment achieved by Weaver and Lobkis (2001) in a sample of duralumin, other demonstrations have been performed in bounded media. For example, acoustic propagation in underwater waveguides is bounded by the air–water and water–bottom interfaces that justify the presence of propagating modes. Different authors have studied the convergence of the correlation function toward the Green's function in underwater acoustics, with some successful applications to array element synchronization or bottom mapping.

1.12.4.5 Equipartition and Random Fields

As Earth is a complex medium, scattering by small-scale heterogeneities is a relevant phenomenon to understand seismic-wave propagation, particularly for short period waves in the lithosphere. Scattering is revealed at the first order by the amplitude decay of the direct arrivals and by the long coda of seismograms. For coda waves, multiple scattering must be taken into account. This is a general issue in different domains that has led to considerable developments aimed at the quantitative description of the spatial and temporal evolution of the local energy, or intensity, of the scattered field, via the diffusion approximation or the more general radiative-transfer equation (see Sato et al., 2012, for a review on seismic waves). While the average energy density is successfully predicted by these theories, the phases, that is, the details of the wave shapes, are assumed to be unpredictable random variables. At the same time, the deterministic phase of the waves that is neglected in the theory for energy or intensity is clearly expressed in phenomena such as coherent backscattering (Larose et al., 2004) and long-range correlations in the form of the Green's function (Campillo and Paul, 2003).

For waves propagating in the heterogeneous Earth, the diffusive regime emerges after several scatterings at a time that depends on the scattering strength of the medium (e.g., Sato et al., 2012). Asymptotically for large times, the wavefield is expected to consist of random contributions of all the possible modes of propagation, with equal weights on average (e.g., Ryzhik et al., 1996; Weaver, 1982). This state is referred to as equipartition. Note that we refer here to the modes of a fictitious model close enough to the actual complex Earth to essentially share the same propagation properties (e.g., Campillo and Margerin, 2010). In a realistic medium, the propagation modes are associated with complex eigenfunctions. Equipartition, therefore, does not imply that their contributions are the same everywhere. At a given observation point, equipartition results in a constant ratio of the relative contributions of the P-waves and S-waves to the time-dependent diffuse local energy, independent of the detail of the scattering. The stabilization of the S-to-P energy ratio is observed in the coda of actual seismograms (Hennino et al., 2001; Margerin et al., 2009; Yamamoto and Sato, 2010). This is a good indication that the wavefield has entered into a regime where the diffusion approximation can be applied to describe the average energy density.

Equipartition and isotropy are asymptotic states of diffuse fields for large lapse times. Indeed, these conditions are generally not reached in practice. In the presence of a single source, the overall divergent flux of energy precludes a perfect isotropy of the flux even for large lapse times. It must be noted that although it is an indicator of the diffusion, the stabilization of the energy ratios is not synonymous with equipartition and, therefore, isotropy of specific intensity (Paul et al., 2005).

We recast here a plausibility argument for the construction of Green's function from correlation of diffuse fields that was originally proposed by Lobkis and Weaver (2001). In the case of a finite body, a diffuse field can be expressed in terms of the normal modes $U_n(\vec{r})$ as

$$\phi(\vec{r};t)=\sum_n a_n U_n(\vec{r})\cos(\omega_n t) \qquad [54]$$

where the complex amplitudes a_n are uncorrelated random variables, such that

$$\langle a_n a_m^*\rangle=F(\omega_n)\delta_{nm} \qquad [55]$$

where $F(\omega)$governs the shape of the spectral energy density. The cross-correlation of the two fields at points $\vec{r}_1$ and $\vec{r}_2$ is

$$C_{1,2}(t) = \frac{1}{T}\int_0^T \phi\left(\vec{r}_1,\tau\right)\phi\left(\vec{r}_2,t+\tau\right)\mathrm{d}\tau \qquad [56]$$

Assuming a long recording interval T, this reduces to

$$C_{1,2}(t) = \frac{1}{2}\sum_n F(\omega_n)U_n\left(\vec{r}_1\right)U_n\left(\vec{r}_2\right)\cos\left(\omega_n t\right) \qquad [57]$$

This expression of the correlation function must be compared to the Green's Function:

$$G\left(\vec{r}_1,\vec{r}_2;t\right) = \sum_n U_n\left(\vec{r}_1\right)U_n\left(\vec{r}_2\right)\frac{\sin\left(\omega_n t\right)}{\omega_n}\Theta(t) \qquad [58]$$

For positive times, $C_{1,2}(t)$ and $G(\vec{r}_1, \vec{r}_2; t)$ differ only by a time derivation and the spectrum of the diffuse field. While limited to the case of finite bodies, this simple demonstration is a justification for the pioneering experiments performed in acoustics by Lobkis and Weaver (2001).

1.12.4.6 Example with Elastic Waves

In the homogeneous 2D case with surface waves discussed in Section 1.12.4.1.1, the wavefield is projected on plane waves that propagate in every direction with constant amplitude. The equipartition then reduces to isotropy. The correlation of an equipartioned field at two points, therefore, reduces to the case discussed in Section 1.12.4.1. The elastic case is more informative.

In the elastic 2D case, the equation of motion for the velocity vector $\vec{u}$ is

$$\beta^2\frac{\partial^2 u_i}{\partial^2 x_j} + \left(\alpha^2-\beta^2\right)\frac{\partial^2 u_j}{\partial x_i \partial x_j} = \frac{\partial^2 u_i}{\partial^2 t} \qquad [59]$$

where u_i is one component of the velocity vector, and α and β correspond to the P-wave and S-wave velocities, respectively.

Assuming a homogeneous medium, we project the elastic wavefield on the P and S plane waves. For the 2D case, the ratio of S-wave to P-wave energies of an equipartioned field can be obtained by a simple mode-counting argument:

$$\frac{E_S}{E_P} = \frac{\alpha^2}{\beta^2} \qquad [60]$$

Let us consider an isotropic 2D field in which P-waves and S-waves are propagating in all directions, with the spectral densities S^2 and P^2 independent of the direction of propagation. We denote the wavenumber for the P-waves and S-waves by $\vec{q}$ and $\vec{k}$, respectively.

Following Sánchez-Sesma and Campillo (2006), we assume an energy ratio between the S-waves and P-waves such that $\varepsilon\frac{E_S}{E_P} = \frac{\alpha^2}{\beta^2}$ with $\varepsilon = 1$ for equipartition. We consider the cross-correlation of the resulting field $\vec{u}$ at positions $\vec{x}$ and $\vec{y}$. We assume $\vec{y}$ to be at the origin. Position $\vec{x}$ is written as $(x_1 = r\gamma_1, x_2 = r\gamma_2)$. After averaging over the incidence direction for an isotropic plane wave distribution, the correlation can be written as

$$\left\langle u_i\left(\vec{y};\omega\right)u_j^*\left(\vec{x};\omega\right)\right\rangle = \frac{S^2\beta^2}{2}\left[A\delta_{ij} - B\left(2\gamma_i\gamma_j - \delta_{ij}\right)\right] \qquad [61]$$

where

$$A = \varepsilon\frac{J_0\left(\left|\vec{q}\right|r\right)}{\alpha^2} + \frac{J_0\left(\left|\vec{k}\right|r\right)}{\beta^2};$$
$$B = \varepsilon\frac{J_2\left(\left|\vec{q}\right|r\right)}{\alpha^2} + \frac{J_2\left(\left|\vec{k}\right|r\right)}{\beta^2} \qquad [62]$$

When the equipartion energy ratio is assumed, that is, $\varepsilon = 1$ in eqn [60], we recognize the exact compact form of the 2D elastic Green's function, and the cross-correlation is simply given by (Sánchez-Sesma and Campillo, 2006):

$$\left\langle u_i\left(\vec{y};\omega\right)u_j^*\left(\vec{x};\omega\right)\right\rangle = -8E_S k^{-2}\mathrm{Im}\left[G_{ij}\left(\vec{x},\vec{y};\omega\right)\right] \qquad [63]$$

where $E_S = \rho\omega^2 S^2/2$.

Note that in this particular case, we use the definition of the Green's function for the elastodynamic equation (eqn [59]) as the response in the displacement to a unit force. This simple canonical case can be extended to 3D and illustrates the close relation between equipartition of the wavefield and the extraction of the Green's function from the cross-correlations.

In the literature, different definitions of the equipartition are presented that can depend on (1) the use of a time-domain or frequency-domain approach; (2) the properties of the propagation medium (open or bounded medium, presence of scatterers); and (3) the nature of the incident wavefield (stationary random noise, spatial distribution of pulsed sources, plane waves, or modal excitations). Even though equipartitioning is at the basis of the noise correlation theorem, all situations are not equivalent. For example, we will consider in the next paragraphs and in practical applications some cases where parts of the Green's function can be extracted in the absence of equipartitioning.

1.12.5 Practical Limitations

1.12.5.1 Partial Focusing

We have seen that the correlation of an even distribution of sources can lead to the Green's function of the medium. Indeed, in the actual application of ambient-noise correlation, the sources are likely to result in a form of non-isotropy of the incoming flux to the pair of stations of interest. In this case, it cannot be expected that the exact response of Earth will be retrieved. It is important to determine how an improper distribution of the source affects the cross-correlation, and how reliable the measurements of travel times or of amplitude become.

We start with an intuitive argument that follows the time-reversal analogy presented in the Introduction. Figure 6(a) shows a numerical test similar to that in Figure 1, except for the distribution of the sources. The sources are now located along a segment (Figure 6(a)), which offers poor azimuthal coverage of the medium. The presence of scattering partly compensates for this uneven distribution of the sources. We now observe a relatively poor focusing and a clearly different pattern of snapshots at positive and negative times. Figure 6 illustrates clearly the impact of the physical flux of energy on the reconstruction. The reconstructed Green's function does not show the expected temporal symmetry. Furthermore, for

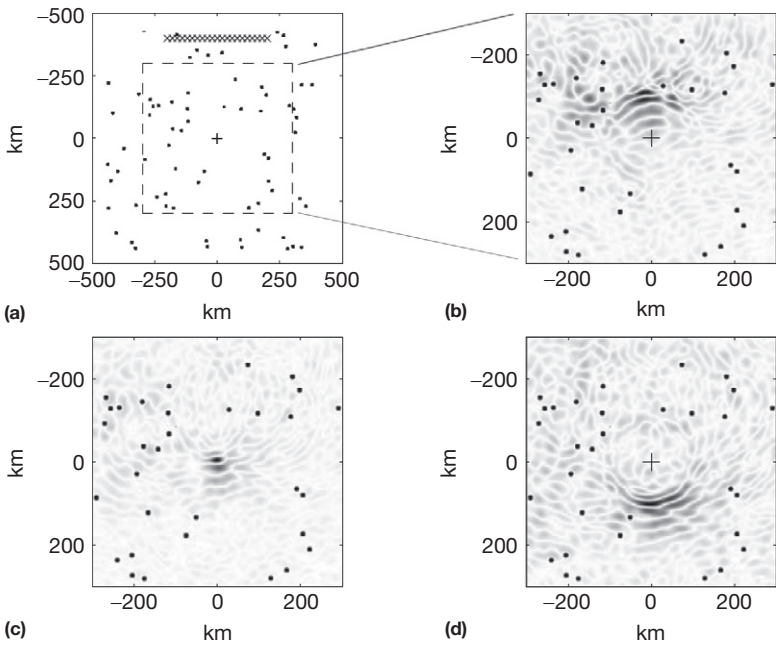

Figure 6 Snapshots of cross correlations with respect to the field at the center (+), as in **Figure 1**, but with a distribution of sources limited to a line ((a), × symbols). (b), (c), and (d) correspond to correlation times of −30, 0, and 30 s, respectively.

receiver pairs oriented perpendicular to the flux, there is no detectable trace of the propagating wave.

Therefore, it is clear that, in general, correlations of noise cannot be considered directly as actual Green's functions for imaging purposes. The distribution of the noise sources has to be considered as a constituent of observables, such as arrival times or amplitudes. This can be formulated explicitly for a general imaging approach in the expression of the sensitivity kernels for noise correlations (Hanasoge, 2013; Tromp et al., 2010). In practice, the space–time distribution of the noise sources is not known precisely. With simple assumptions, it is, nevertheless, possible to quantitatively determine the bias between noise correlations and true Green's functions.

1.12.5.2 Travel Time Measurements

Even when a propagating wave is identified, it is important to quantitatively evaluate the quality of the measurements that can be performed when the distribution of sources leads to nonisotropic illumination of the station pairs. Let us consider a simple 2D case where a pair of stations is surrounded by a distant distribution of incoherent sources that leads to nonisotropic specific intensity (Weaver et al., 2009). This is a geometry of interest when dealing with surface waves from distant noise sources (Tsai, 2009).

We assume that we measured the derivative of the correlation between the signal observed at the two receivers over the angle θ between the direction of incidence and the strike of the two receivers (**Figure 3(c)**). $B(\theta)$ is the azimuthal distribution of the energy of the sources, and it can be expanded as

$$B(\theta) = B_0 + B_1 \cos\theta + B_2 \cos 2\theta + \cdots \qquad [64]$$

Note that only even terms contribute to this problem, because of the symmetry of the apparent velocity with respect to $\theta = 0$.

Let us consider the case of distant receivers, that is, $kx \gg 1$. We are in the high-frequency limit where the contributions to the correlations are dominated by the contributions of the end-fire lobes, that is, $\theta \simeq 0$. The goal is to evaluate the time error that is induced by the anisotropy of the sources. To be under conditions useful for seismological applications, the induced bias (delay) δt is evaluated as the time of the maximum of the cross-correlation between a Gaussian pulse of central frequency ω_0 in the isotropic source ideal case ($B(\theta) \equiv 1$) and that of the nonisotropic case. Under the high-frequency approximation, it can be shown that (Weaver et al, 2009)

$$\delta t = \frac{B''(\theta = 0)}{2t\omega_0^2 B(\theta = 0)} \qquad [65]$$

where $B''(\theta)$ refers to the second-order derivative of $B(\theta)$.

These formulae indicate that the error decays with frequency and with interstation distance. This is in agreement with the conclusion of Yao and van der Hilst (2009). The decay of the bias with interstation distance can be understood as the diminution of the angular size of the end-fire lobes with increasing distance.

The stationary phase theorem helps in the interpretation of the physics aspect of this observation (see **Section 1.12.3.2**). Only the sources almost in the alignment of the receivers can contribute to the reconstruction. The aperture of the zone where the coherent sources are located varies with the square root of the ratio between the wavelength and the distance between the receivers. At higher frequencies, the end-fire lobes are narrower (Larose et al., 2005; Roux and Kupermann, 2004; Spetzler and Snieder, 2004) and the correction term is smaller. For simplicity, only the positive correlation time has been discussed here, but the argument is the same for negative time, and a formula similar to eqn [65] is obtained with direction π instead of 0.

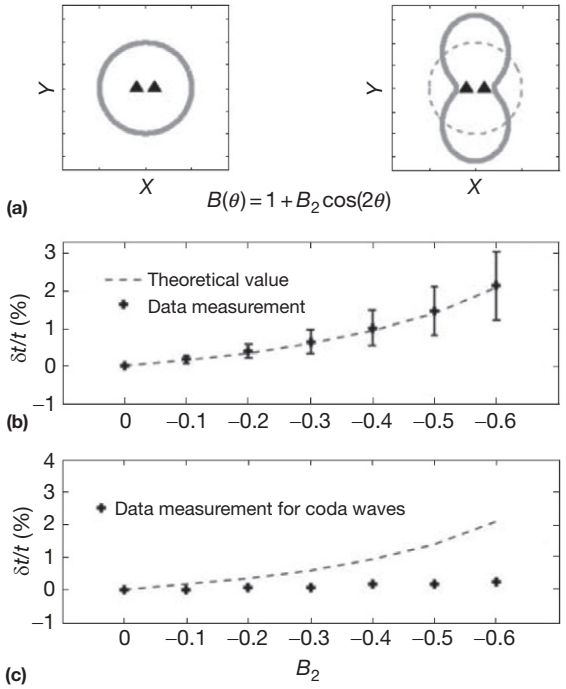

Figure 7 Bias in travel time measurements for a source amplitude distribution of the form B. Different values of B_2 then correspond to different source intensity distributions. (a) Shape of the azimuthal distribution for $B_2 = 0$ (left panel, isotropic distribution) and $B_2 = -0.6$ (right panel, anisotropic distribution). (b) Correlations of direct waves as defined in **Figure 3(b)**. Measured (crosses) and predicted (dashed line) relative time shifts for B_2 ranging from 0 to −0.6. The theoretical values result from eqn [65]. Error bars correspond to standard deviations of 18-pair measurements. The reference travel time corresponds to the correlation function obtained for an isotropic distribution of sources. (c) The same measurements as in (b), but with cross-correlations of time windows that correspond to coda waves (**Figure 3(b)**).

These formulae have been validated numerically and experimentally. Froment et al. (2010) used actual Green's functions obtained during the seismic exploration experiment presented in **Section 1.12.3.2** (**Figure 3**), and they found excellent agreement between observation and theory. This is illustrated in **Figure 7**, which shows the evolution of the travel time bias with increasing anisotropy of the incoming field. The anisotropy of intensity is produced by a modulation of the amplitude of individual source records of the form $B(\theta) = 1 + B_2 \cos(2\theta)$, where θ is defined as in the insert of **Figure 3(b)**. B_2 varies from 0 (isotropy) to −0.6. The two extreme cases are plotted in **Figure 7(a)**. To be under the conditions of the theoretical formula (eqn [65]), the correlations are computed for the direct waves (**Figure 3(b)**), weighted according to $B(\theta)$ for each source, and then averaged over the set of sources. **Figure 7(b)** shows the very good agreement between the theoretical expectations given by eqn [65] and the actual measurements.

1.12.5.3 Amplitude and Spreading

When the conditions for the perfect reconstruction of the Green's function are fulfilled, the amplitude of correlation can be used to study the attenuation properties along the path, or the local amplification produced by specific local geological structures. **Figure 6** shows how an uneven distribution of sources results in poor focusing in a simple medium for a scalar problem. It is noticeable that poor focusing means that the natural curvature of the Green's function wave front is not correctly reconstructed and that, consequently, the geometrical decay of amplitude is not reproduced. In general cases, it is dangerous to mix noise cross-correlations for pairs in different azimuths to retrieve the attenuation properties of the crust.

The simplest case of illumination by a plane illustrates the specific difficulty associated with decay measurements. This occurs when a strong localized source is acting far away from the two receivers. If the noise includes such a predominant plane wave propagating in the direction of the two receivers, the cross-correlation is not the Green's function, although the time of transport of energy is the same, even if the phase is not retrieved correctly (see **Section 1.12.4.1**). The effect is obviously much more severe for the amplitude, as the plane wave has no geometrical spreading, in contrast to the Green's function. Attenuation measurements would be strongly biased by this effect, which cannot be corrected by energy normalization (e.g., Gouédard et al., 2008a).

It was, nevertheless, convincingly shown by Prieto et al. (2009) and Lawrence and Prieto (2011) that attenuation studies can be performed with ambient noise. These authors used the coherency, a normalized version of the cross-correlation, in place of correlation (see **Section 1.12.6**). A discussion of the feasibility and limitations of attenuation studies with ambient noise is presented in Prieto et al. (2011) and Weemstra et al. (2013).

Considering only the reconstruction of the direct waves in the scalar case can hide some difficulties that arise in practical applications, with ambient noise or with active sources at the surface. In the presence of several waves (P and S, reflections) and imperfect illumination, the correlation can show pulses associated to stationary-phase conditions, but not to physical arrivals. These spurious arrivals correspond to correlation times of waves of different natures, that is, which are not propagating between the two points of observations. For a distribution of sources at the surface, Snieder et al. (2006) give an example of interest for exploration. They considered a simplified case with two reflections at different depths. When considered as a function of the position of the source, the difference in travel time between the two reflected waves at the receivers had a maximum at a finite distance. According to the stationary-phase argument, a spurious arrival can, therefore, be expected at a time that is actually a difference of travel time between the reflector levels at depth, without significance for the actual paths between the receivers. Indeed, this problem vanishes if the source distribution extends at depth, or if scatterers acting as sources mimic an even distribution of sources.

1.12.5.4 Influence of Scattering

Although it is impossible to directly separate the contributions of direct and scattered waves in the ambient noise produced by a distribution of uncorrelated sources, we can easily evaluate the behavior of the correlation of scattered waves in the experiment presented in **Section 1.12.5.2** and in **Figure 7**. The results of **Figure 7(b)**, which were obtained with direct waves, were repeated for the correlation of coda windows as

defined in Figure 3(b). The resulting measurements are presented in Figure 7(c) as a function of the anisotropy coefficient B_2. The bias in travel time observed for coda-wave correlations is much smaller than for the case of direct waves. In the worst case, that is, $B_2 = -0.6$, $\delta t/t$ only reaches 2×10^{-3}. This is due to the smooth azimuthal distribution of the intensity of the coda waves. This shows the important part played by scattered waves for the effectiveness of the correlation method.

1.12.6 Processing

1.12.6.1 Processing and Convergence

The basic expectation when correlating noise time series is that for long times of observation, the noise source distribution is averaged toward a distribution that is acceptable with respect to the mathematical requisites discussed in Section 1.12.4. An obvious difficulty is the presence of strong energy transients that potentially dominate in the correlation. Those transients can be large earthquakes, local storms in the microseism spectral band, or various other sources, depending on the frequency range considered. Different strategies are used to improve the temporal stationarity of the records before correlation.

The first possibility is to remove the time windows with earthquakes. This can be done from earthquake bulletins, at least for large events. In practice, a detection algorithm is required to identify small events if no further normalization is applied.

Indeed, strong direct waves generally contribute to nonphysical signals in the correlation. On the other hand, the scattered waves of the coda are a valuable contribution to the reconstruction of the Green's function. As the duration of the coda is much longer than that of the direct waves, efficient processing consists in the normalization of the signal. This normalization is necessary in most cases, even after earthquake rejection.

One-bit normalization was used for the correlation of seismic codas by Campillo and Paul (2003), to balance the temporal exponential decay of the intensity in the coda. This was then used in numerous studies on noise correlation (e.g., Cupillard et al., 2011; Shapiro and Campillo, 2004; Shapiro et al., 2005). That the correlation function of two hardly clipped signals is very close to that of the original signals has been discussed in detail in communication theory (e.g., van Vleck and Middleton, 1966). The numerical simulations of Cupillard and Capdeville (2010) showed that even geometrical spreading and attenuation can be retrieved from correlations of 1-bit clipped data. Instead of using 1-bit correlation, Sabra et al. (2005a) introduced a clipping procedure to limit the contribution of high-amplitude transients, while leaving the background noise unaffected. Bensen et al. (2007) proposed to apply a running-average procedure to ensure the temporal stationarity.

Instead of affecting the data by a form of nonlinear processing, Prieto et al. (2011) and Poli et al. (2012b) proposed to use short time windows, as short as 1 h, to compute the correlation. Transients can be removed after statistical analysis of the total energy of the signal in all the windows. Each correlation is normalized according to its energy before stacking.

Sabra et al. (2005a) analyzed the quality of the reconstruction for a set of station pairs within a range of 180–220 km in Southern California, USA. As shown in Figure 8(a), the cross-correlations are relatively stable over time, as seen for each day of July 2004 for a single station pair. While there are some fluctuations in the small-amplitude waveforms, the main arrivals are stable. The SNRs for each day and each station pair show moderate variations as the noise and seismicity varies. We sum the cross-correlation time series for each day to obtain the time series for N number of days and to compute the SNR (Figure 8(b)). Each day is treated as an independent observation and, therefore, for each N the sum is computed for all the combinations of the 18 days. The accumulated SNR based on the summed traces shows clearly that the SNR increases in proportion to the square root of the recording time, in agreement with Sabra et al. (2005a) and Snieder (2004).

Larose et al. (2008) studied the role of scattering in the convergence toward the Green's function. In this context, the SNR is the ratio between the level of signal in the correlations and the level of remnant fluctuations. They analyzed the SNR dependence in the context of a discrete random distribution of noise sources in a scattering medium. Indeed, the SNR increases with the number of sources. When scattering is present, the SNR increases with scattering strength. This is due to the increase in the duration of the individual source signals with stronger scattering, in addition to the previously discussed isotropization of the intensity. Disorder here improves the quality of the reconstruction. On the contrary, the SNR is directly dependent on the amplitude of the actual Green's function. The amplitude decreases with travel time or distance, and it is sensitive to scattering and absorption.

As the ambient noise spectrum in the microseism band shows clear peaks, it is convenient to introduce spectral whitening (e.g., Bensen et al., 2007). The nature of a seismogram being nonstationary, it is natural to introduce multidimensional filtering to denoise the correlations. Adaptive filtering based on the S transform (Stockwell et al., 1996) was used by Baig et al. (2009), while Schimmel et al. (2011) proposed the use of instantaneous phase coherence to weigh the stack of individual correlations.

Stehly et al. (2011) used filters in the curvelet transform space to improve the SNR of stacked correlations. The previous approaches were based on the use of signal-processing tools. A physics-based approach can be expected to improve the reconstruction. In the noise-correlation context, this consists in minimizing the effects of the nonisotropic illumination. This was done by using an optimization scheme, which was referred to as multidimensional deconvolution by Wapenaar et al. (2008), or as a passive inverse filter by Gallot et al. (2012).

Velocity measurements and the evaluation of their uncertainties can be improved by using the nine correlations obtained with three-component records, with each correlation being defined for positive and negative times. The correlation matrix is expected to show the symmetry of the Green's tensor (e.g., Campillo and Paul, 2003; Sabra et al., 2005b). For practical applications, the computation of the complete correlation matrix allows redundant measurements to be made of Rayleigh wave velocities and their variance (e.g., Stehly et al., 2009).

1.12.6.2 Correlation of Correlations

We have seen that the cross-correlation function of long ambient-noise time series can be identified as the sum of the

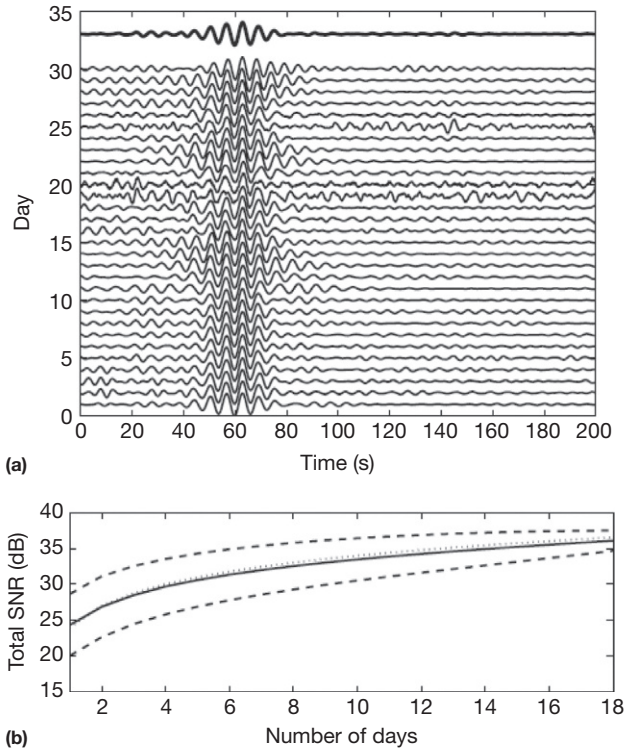

Figure 8 (a) Estimated noise correlation function for one station pair at a distant of 182 km, for each day of July. The summed trace for the whole month of July is shown as the thick solid line. (b) Mean and standard deviations of the SNR (in dB scale) computed by summing all the combinations of the correlation functions over a number of days. The square root dependence is shown as a dotted line. Reproduced from Sabra KG, Gerstoft P, Roux P, Kuperman WA, and Fehler MC (2005) Extracting time-domain Green's function estimates from ambient seismic noise. *Geophysical Research Letters* 32: L03310. http://dx.doi.org/10.1029/2004GL021862.

causal and acausal Green's function. So far, we have discussed the reconstruction of ballistic arrivals. The Green's function also contains the late arrivals associated with scattered waves. According to the discussion in **Section 1.12.4**, these arrivals are also expected to be present in the noise cross-correlations, as has been verified with numerical simulations (e.g., Derode et al., 2003a,b). In the ideal case, the later part of the noise correlation should contain the coda part of the Green's function, and it might be possible to correlate these waves as we correlate standard earthquake codas, to reconstruct the Green's function (Campillo and Paul, 2003). This is the concept of the so-called C^3 method; that is, re-correlating the *c*oda of the noise-*c*orrelation functions to reconstruct the Green's function (Froment et al., 2011; Ma and Beroza, 2012; Stehly et al., 2008). Garnier and Papanicolaou (2009) demonstrated the validity of this method based upon stationary-phase analysis of the C^3 function leading terms, and they confirmed that this method can enhance the quality of travel time estimates in the case of anisotropic source distributions.

For a network of N stations, the C^3 function between two stations A and B is computed through the successive steps illustrated in **Figure 9**. Let a third station in the network be represented by S. The noise correlation is computed between A–S and B–S (**Figure 9(a)**, C^1). The noise correlation corresponds to the signals recorded at A and B, respectively, if a source was present at S. The receivers S have the role of virtual sources. The same operation is repeated for all of the stations S in the network. A time window in the later part of the noise correlations is selected (at twice the Rayleigh wave travel-time in Stehly et al. (2008)). Note that the codas for both the positive and negative parts of the noise correlation are selected. The correlations of the codas of the A–S and B–S noise correlations are computed for positive and negative times. The results are finally averaged for all of the virtual sources S of the network to obtain the C^3 function between A and B (**Figure 9(b)**).

Note at this point that the geometry of the network controls the illumination of virtual sources for the C^3 computation. With this procedure, Stehly et al. (2008) showed that C^3 shows the ballistic Rayleigh waves of the Green's function, as demonstrated for actual coda-wave correlations (Campillo and Paul, 2003). This demonstrates that the late part of the ambient-noise correlation function contains a physical signal, namely, the scattered coda waves. This is important, as it opens the way for using this signal for further applications (see **Section 1.12.7.2**).

Froment et al. (2011) illustrated the concept of a virtual source used for C^3 computation. They compared the time symmetry of both correlation functions (C^1 and C^3) for the particular case of the station pair of HAU–BOURR, as illustrated in **Figure 10**. In the C^3 correlation process, only the 55 network stations south of HAU–BOURR were considered (see **Figure 10(a)**). The noise records were filtered in the frequency band from 0.1 to 0.2 Hz.

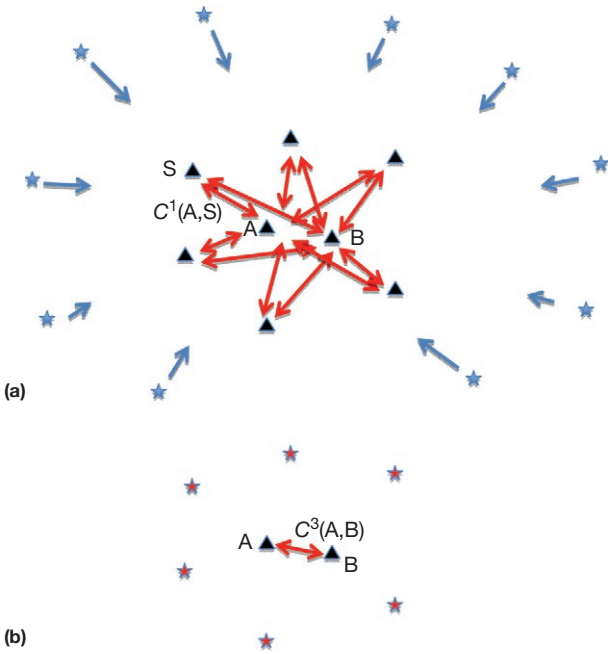

Figure 9 From the noise correlations (C^1) to the correlation of correlations C^3. (a) Construction of the noise cross-correlations (red arrows) between stations A and B and all the other stations S of the network. The blue stars represent distant sources of noise. (b) Construction of C^3 between A and B using the stations of the network as virtual sources (red stars).

This means that the theoretical C^3 virtual sources are located south of the station pair of interest and opposite to the incident-noise direction, as the main source of noise is located in the North Atlantic Ocean or on the northern European coast (e.g., Friederich et al., 1998; Kedar et al., 2008; Landès et al., 2010; Stehly et al., 2006). **Figure 10(b)** shows the results of both the C^1 and C^3 correlation functions for this geometry. The time symmetry of both the signals shows two opposite peaks of maximum amplitude, which reflect a main energy flux that propagates in opposite directions: from north to south for C^1, and from south to north for C^3. Note that the same convention is used for all the correlation functions, that is, the signal in negative (respectively, positive) correlation times corresponds to waves propagating from north to south (respectively, south to north). This observation indicates that the time symmetry of the two correlation functions is consistent with the location of their expected contributing source distributions (actual or virtual). However, the C^3 function has a better time symmetry than C^1. This indicates that the coda waves used to compute the C^3 function constitute a more isotropic field than the ambient seismic noise. Back-scattered waves produce a north-to-south energy flux propagation and, therefore, contribute to a clear pulse in the negative correlation times.

Furthermore, Froment et al. (2011) also discussed the possibility of using the C^3 coda to reconstruct part of the Green's function. They computed a C^5 function, the *c*orrelation of the *c*oda of C^3, and found that the Rayleigh wave is reconstructed. This shows that some coherent signal is still present in the coda of the C^3 function. This result supports the idea that the C^5 function can also be used in noise-based tomography or for monitoring techniques. However, the SNR in the C^5 function is smaller than that in the C^3 function, because of the reduction in the time-window length used for the computation of the correlation. This might limit the practical interest in this iterative correlation process.

The computation of the correlation of correlations is a way to control the illumination, and its isotropy, by using a network of stations as part of the virtual sources. Furthermore, it allows for the separation of scattered and direct waves for the final correlation. This selection is obvious with the selection of an ad hoc time window in noise correlations. From the opposite side, it is impossible to perform this separation with noise records in which direct and scattered waves from various sources are mixed. Although the coda of correlation takes advantage of the properties of multiply scattered waves, it is also possible to compute the correlation of complete noise correlations, including the ballistic part (Froment et al., 2011). This is indeed of interest for long-period waves for which the scattering is weak. The distribution of the stations, which play the role of virtual sources, is the determinant in this case.

Ma and Beroza (2012) used the C^3 approach with data from stations that operate asynchronously, showing that it is practically possible to complement the virtual network with stations that were recording at different periods. Curtis and Halliday (2010) presented a series of integral relations essentially based on correlation or convolution of correlation functions that allowed for reconstructions of virtual seismograms from non-synchronous records; that is, a record at a station that was not operating at the time of an event. Curtis et al. (2012) showed the application of these principles for an earthquake in New Zealand.

1.12.7 Applications

1.12.7.1 Surface-Wave Tomography

It is generally assumed that noise is related to surface activity, which ranges from human activity at high frequency to the forcing of the oceans and the atmosphere at low frequency. As a consequence, the seismic noise observed at the surface has a strong component of surface waves, as has the Green's function between two surface points. The first attempts to extract the Green's function from coda or noise seismic records demonstrated the retrieval of surface waves (Campillo and Paul, 2003; Shapiro and Campillo, 2004). Numerous studies have confirmed that Rayleigh waves are easily retrieved from ambient-noise correlations. When surface waves are identified in ambient-noise correlations, the methods previously developed for earthquake records can be used to infer dispersion properties and, eventually, tomographic images. Ambient-noise surface-wave measurements have been extensively used for tomography at the crustal and lithospheric scales (e.g., Kang and Shin, 2006; Li et al., 2010; Lin et al., 2009; Nishida et al., 2008b; Poli et al., 2012c; Ritzwoller et al., 2011; Sabra et al., 2005b; Saygin and Kennett, 2010; Shapiro et al., 2005; Stehly et al., 2011; Verbeke et al., 2012; Yang et al., 2007; Yao et al., 2008; Zheng et al., 2008). Anisotropy has also been

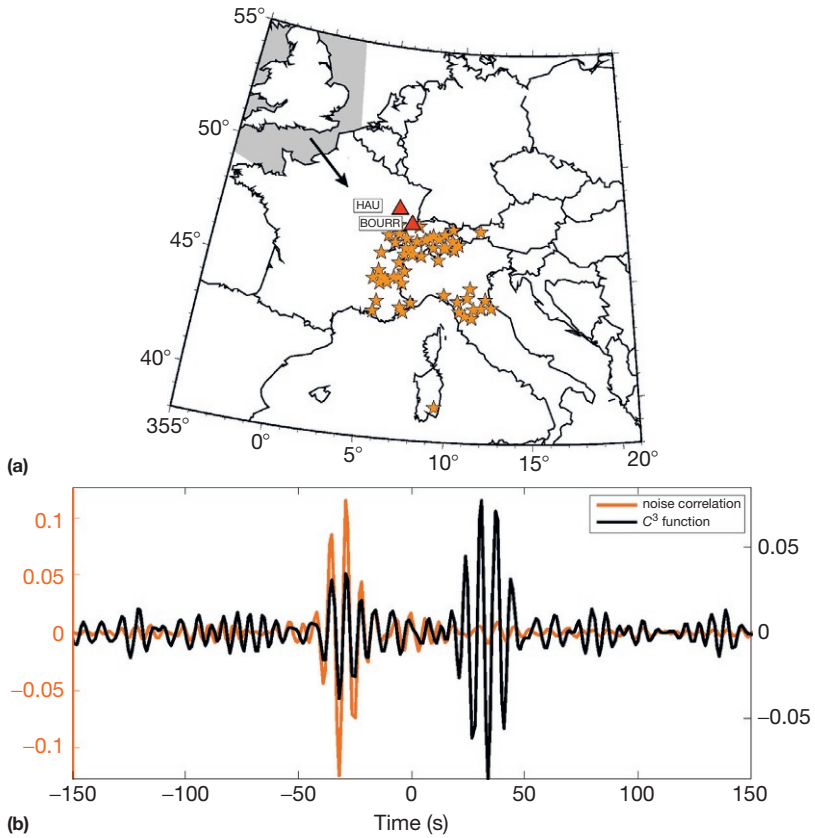

Figure 10 (a) Map of Europe with orange stars corresponding to the 55 stations of the network used as virtual sources to construct the C^3 function between stations HAU and BOURR (red triangles). Note that all the stations considered are located south of the HAU–BOURR path and opposite to the main source of noise located in the North Atlantic Ocean or on the northern European coast (gray zone). The black arrow indicates the main direction of ambient seismic noise in the vicinity of the station pair HAU–BOURR. (b) Noise correlation C^1 (orange curve) and C^3 (black curve) functions between stations HAU and BOURR for the geometry displayed in (a). Note the different vertical scales (left and right, respectively) for the two normalized correlation functions. Reproduced from Froment B, Campillo M, and Roux P (2011) Reconstructing the Green's function through iteration of correlations. *Comptes Rendus Geoscience* 343(8–90): 623–632. http://dx.doi.org/10.1016/j.crte.2011.03.001.

inferred (e.g., Huang et al., 2010; Ritzwoller et al., 2011). Harmon et al. (2007) and Yao et al. (2011) studied the oceanic lithosphere with ambient noise records from ocean bottom seismometers.

Ambient-noise tomography takes advantage of the dense networks by providing a large number of interstation measurements. This allows for improved resolution with respect to using distant earthquake records. This is particularly true for the short periods that are difficult to use when dealing with distant sources. With large dense networks, specific approaches can be applied. An example was presented by Ritzwoller et al. (2011) with eikonal tomography. This technique is based on direct measurement of the local velocity of a surface wave. This is achieved by the use of the eikonal equation, with maps of travel times measured and interpolated on a dense array. In the context of ambient-noise tomography, this operation can be performed with each station acting as a virtual source. When considering all possible virtual sources, a map of the seismic speed can be built, as a function of the azimuth of propagation. An application of these principles is illustrated in **Figure 11**, where the dense array of western United States is used to build a high-resolution map of Rayleigh wave speeds at 24 s, and a map of the amplitude of anisotropy and the direction of the fast axis (Ritzwoller et al., 2011).

Ambient-noise surface-wave tomography has also been applied successfully at smaller scales, to volcanic structures (e.g., Brenguier et al., 2007), shallow surface layers (e.g., Picozzi et al., 2008), and landslides (e.g., Renalier et al., 2010). It is of note that Larose et al. (2005) reported a study of the lunar subsurface from the ambient noise recorded during the Apollo 17 mission.

1.12.7.2 Body Waves

Although usually with weak amplitudes, body waves are present in the noise records. This was clearly shown with array analysis in recent studies (e.g., Gerstoft et al., 2008, who identified mantle and core phases), and body waves have been used to map the regions where noise is produced at a global scale (e.g., Landès et al., 2010).

There is, therefore, substantial hope of extracting the body-wave part of the Green's function, albeit with a lower SNR than for the dominant surface waves. Actually, body waves have indeed been reported from short-distance range correlations.

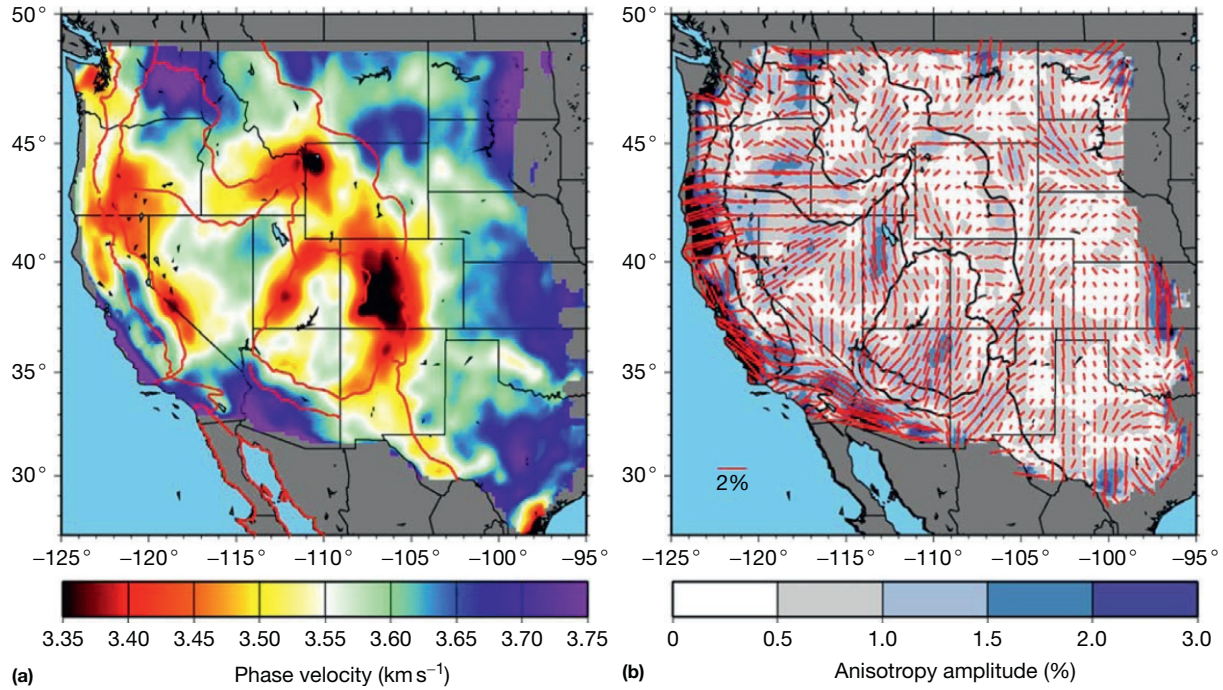

Figure 11 (a) The 24-s Rayleigh wave isotropic phase-speed map taken from the ambient noise by averaging all the local phase-speed measurements at each point on the map. (b) The amplitudes and fast directions of the 2*c* component of the 24-s Rayleigh wave phase velocities. The amplitudes of the anisotropy are given by the lengths of the bars, which point in the fast-axis direction, and the background is color coded. At the 24-s period, the Rayleigh wave anisotropy reflects conditions in a mixture of the crust and the uppermost mantle. Reproduced from Ritzwoller MH, Lin FC, and Shen W (2011) Ambient noise tomography with a large seismic array. *Compte Rendus Geoscience* 343(8): 558–570. http://dx.doi.org/10.1016/j.crte.2011.03.007.

Roux et al. (2005a) identified direct P-waves from noise correlation, using data from a small array in California, USA. Their noise-derived P-waves were linearly polarized, and with an apparent velocity compatible with a known velocity model of the area. Several studies have claimed that there are reflected phases in ambient-noise autocorrelations and cross-correlations. Draganov et al. (2009) used data from oil exploration surveys to extract reflected P-waves from shallow interfaces. Their observations appeared to be in good agreement with the active source reflection response measured in the same area. Tibuleac and von Seggern (2012) reported that a vertical Moho reflection can be identified in autocorrelations in Nevada, USA. Ito and Shiomi (2012) used ambient noise to extract reflections associated with a subducting slab beneath Japan.

Zhan et al. (2010) identified S reflected phases from the Moho interface at the critical distance in two shield areas. Poli et al. (2012b) built a short-period seismic section across Finland from ambient-noise correlation. They used the continuous records of 42 temporary broadband three-component stations located in the northern part of the Fenno-Scandian region (**Figure 12(a)**). Here, they identified high-frequency body waves (0.5–2.0 Hz) emerging from noise correlations for inter-station distances up to 550 km. The comparisons of the noise correlations with earthquake data confirmed that the observed waves can be interpreted as P-waves and S-waves that are reflected from the Moho. As the crustal model of the area is well known, the noise correlations can be compared with synthetic seismograms. **Figure 12** shows an example of such a comparison for two different components of motion: it indicates that the travel times of all the observed phases are in excellent agreement. Poli et al. (2012b) also performed a polarization analysis that confirmed that reflected body waves are positively extracted from ambient noise.

A further step is to demonstrate that deep seismic phases can be retrieved from ambient noise. Poli et al. (2012c) used noise in the microseism band to retrieve P-waves reflected at the top (~410 km deep) and at the bottom (~660 km deep) of the transition zone. **Figure 13** shows the stacked correlations for the pairs of the LAPNet array (see **Figure 12(a)**), as compared with the preferred velocity model. This demonstration that deep interfaces can be imaged with ambient noise at the surface confirms that the ambient noise in the microseism band consists partly of body-waves propagating at the global scale and illuminating the deep interior. This opens the way for the use of ambient-noise correlations to image the deep Earth using body waves. Deep core reflections were reported from correlations at regional distances by Lin et al. (2013). Nishida (2013) and Boué et al. (2013) presented global sections of cross-correlations indicating that most of the deep phases could be extracted from ambient noise.

1.12.7.3 Monitoring

Monitoring of slight velocity changes in Earth can be performed with active sources (e.g., Niu et al., 2008; Reasenberg and Aki, 1974) or with repeating earthquakes (Poupinet et al., 1984; Ratdomopurbo and Poupinet, 1995).

The possibility of using the ambient noise to perform repeated measurements of speeds between fixed stations is

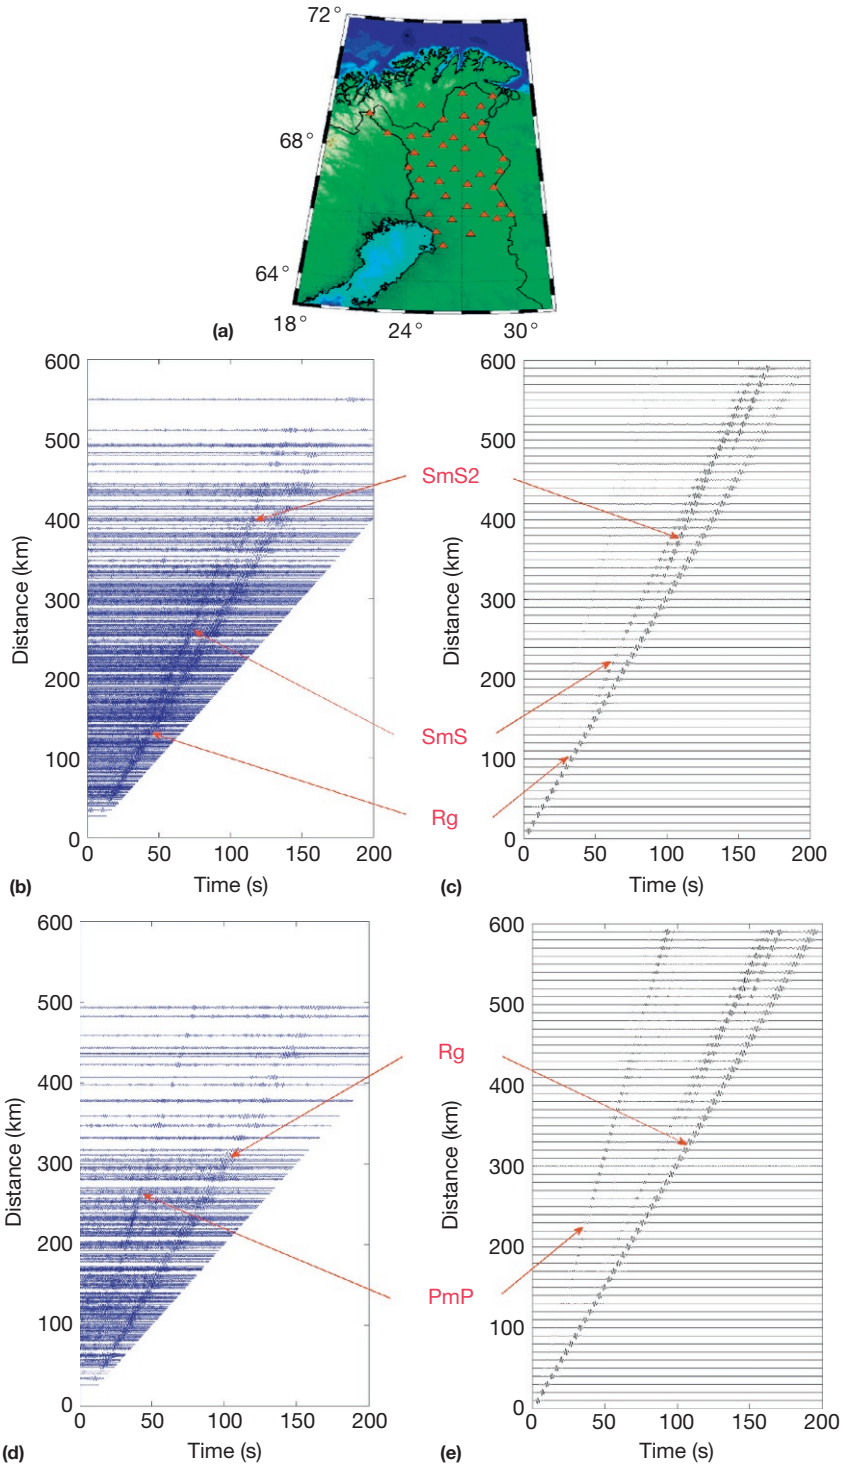

Figure 12 (a) Map of the stations of the LAPNet experiment in Finland. (b) *ZZ* and (d) RR cross-correlations plotted as functions of inter-station distances. Figure 13 (a) Comparison of stacked cross-correlation (data) with synthetic traces computed for the global model AK135, and for the final preferred model beneath Finland depicted in (b). The map of the stations used in this study is shown in **Figure 12(a)**. The figure is modified from Poli P, Campillo M, Pedersen H, and the Lapnet Working Group (2012a) Body wave imaging of the Earth's mantle discontinuities from ambient seismic noise. *Science* 338: 1063–1066.

appealing. In the previous sections, we discussed the convergence of the cross-correlation toward the Green's function for continuous records of ambient noise of finite duration. Careful attention must be paid to the quality of the reconstruction and to the possible bias associated with the angular distribution of the incoming noise energy. With these precautions, it is possible to repeat the processing at different dates and, therefore, to track temporal changes in the medium.

The first requirement is to study the stability of the measurements and to detect possible instrumental errors when using cross-correlations. As the unbiased physical signals should be time symmetric, a comparison of the arrival times in the positive and negative correlation times of the Rayleigh and Love waves allows the separation of time shifts associated with any form of physical change in the medium, so those resulting from clock drift or other instrumental errors, and those caused by changes in the localization of the noise sources (e.g., Stehly et al., 2007). Physical changes in the medium speed result in delays of the same amplitude for positive and negative times. Instrumental changes produce a global shift of the correlation with opposite time delays. Bias caused by non-isotropic illumination (see **Section 1.12.5**) is associated with different noise sources and is not likely to be equal for positive and negative times. These arguments allow for the detection of instrumental errors and for their correction.

Measuring very small relative velocity changes requires the evaluation of delays between traces. Under the assumption of a global change, these delays increase with the travel times, making the detection much easier for large lapse times. For this reason, it is often more difficult to detect small material changes with direct waves than with waves that have sampled the medium for much longer times, as is the case with coda waves.

In **Section 1.12.6.2**, we discussed the properties of the C^3 function. The convergence of C^3 toward the Green's function demonstrates that the late part of the correlation functions contains scattered waves. Sens-Schönfelder and Wegler (2006) found that the envelope of the correlation of noise is similar for the different components of the correlation tensor, as expected for coda waves, and that this envelope can be modeled with a diffusion equation. Indeed, these arguments do not demonstrate that the entire coda is perfectly reconstructed. This is not a requirement to use the correlations for monitoring changes in velocity. With laboratory ultrasound experiments, Hadziioannou et al. (2009) showed that passive monitoring can be successful without complete reconstruction of the Green's function from cross-correlations. While the noise source is variable, it is observed that the late part of the noise correlation function is very stable and allows for the monitoring of slight changes in velocity.

1.12.7.3.1 Velocity change detection and measurement

The delay dt measured before and after a global change in a medium increases linearly with lapsed time t, according to the simple relationship

$$\frac{\mathrm{d}t}{t} = -\frac{\mathrm{d}V}{V} \qquad [66]$$

where $\mathrm{d}V/V$ is the relative velocity change. This is the basis for very precise measurements of velocity change with coda waves. Poupinet et al. (1984) and Snieder et al. (2002) proposed to measure dt in moving windows along seismograms to evaluate $\mathrm{d}V/V$ through linear regression (moving-window cross-spectral analysis, MWSPA). Alternatively, the stretching technique consists of optimization of a stretching parameter ε (e.g., Lobkis and Weaver, 2003; Sens-Schönfelder and Wegler, 2006). The effect of a global small velocity change is to deform the trace by changing the time t by $t' = t(1-\varepsilon_0)$. The strategy is to interpolate the coda at times $t(1-\varepsilon)$ with various stretching factors ε.

The actual relative velocity change is the stretching factor $\varepsilon_0 = \mathrm{d}V/V$ that maximizes the cross-correlation coefficient between the traces that is acquired before and after the change. Hadziioannou et al. (2009) showed that the stretching technique is more adapted to data with low SNRs in the presence of an actual global velocity change.

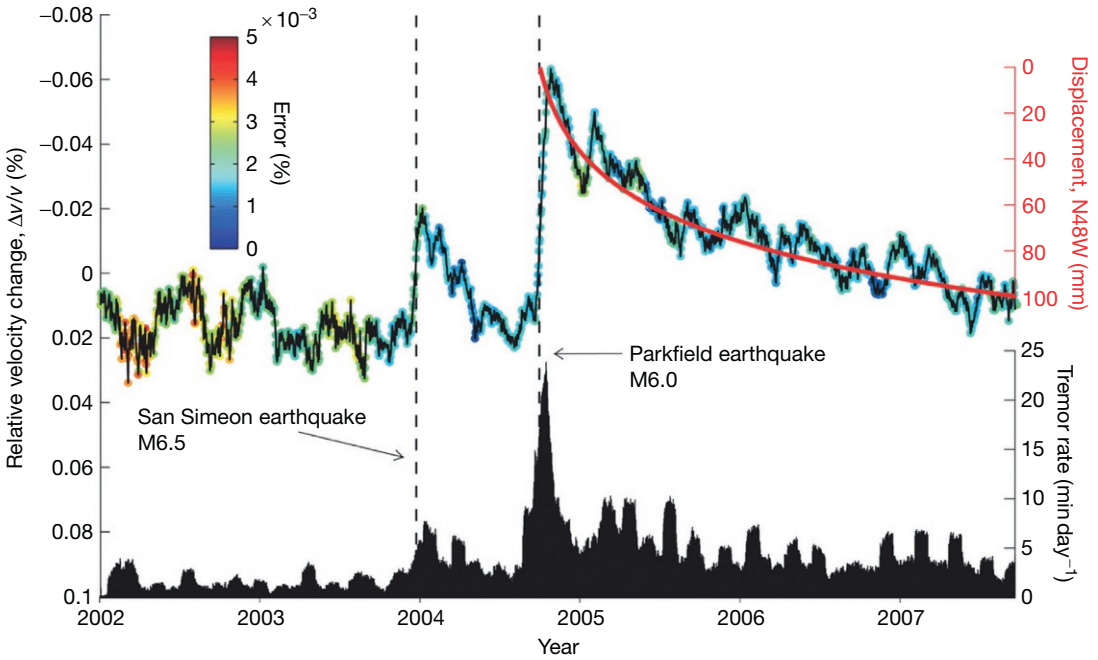

Figure 14 Seismic velocity changes, surface displacements from GPS, and tremor activity near Parkfield. The red curve represents the post-seismic fault-parallel displacements along the San Andreas fault, as measured by GPS at a local station. The tremor rates are averaged over a centered 30-day-long moving time window. Reproduced from Brenguier F, Shapiro NM, Campillo M, et al. (2008) Towards forecasting volcanic eruptions using seismic noise. *Nature Geoscience* 1: 126–130. http://dx.doi.org/10.1038/ngeo104.

Repeated delay measurements have been applied to autocorrelations and cross-correlations, which have demonstrated the possibility to observe relative changes in speed of the medium as small as 10^{-4}. The evaluation of uncertainties is an important issue. Clarke et al. (2011) analyzed the uncertainties of MWSPA in the context of ambient-noise monitoring of a volcano. They concluded that the formal error deduced from the linear regression in MWSPA underestimated the observed fluctuations of velocity when a small amount of noise was added to the correlations. With the stretching method, the dependence of the uncertainty on the correlation coefficient between the traces and the parameters of measure (bandwidth, time window) was given by Weaver et al. (2011).

1.12.7.3.2 Observations

The velocity changes observed with ambient noise are likely to be of various origins. Sens-Schönfelder and Wegler (2006) studied the autocorrelations of noise records on a volcano, and they detected a seasonal velocity change that they interpreted as being related to the variations of the water-table depth. Meier et al. (2010) attributed the seasonal changes of velocity observed in the Los Angeles basin to a thermoelastic effect. Brenguier et al. (2008a) used long time series and detected a velocity change that was a precursor of volcanic eruptions of the Piton de la Fournaise volcano. This was interpreted as the effect of the inflation of the edifice prior to the eruption. Mainsant et al. (2012) also used ambient noise to detect a drop in velocity prior to a landslide.

Recently, several studies have shown the detection of velocity changes associated with the activity of fault systems, earthquakes, and transient creep, with correlations of ambient noise. Wegler and Sens-Schönfelder (2007) detected a change in velocity after the Mw 6.6 mid-Niigata earthquake in Japan. Brenguier et al. (2008b) observed velocity drops associated with two earthquakes in central California, USA (**Figure 14**).

More recently, Hadziioannou et al. (2011) used the adaptive filtering approach of Baig et al. (2009) to improve the time resolution of the monitoring, and they concluded that the velocity drop associated with the Parkfield earthquake is coseismic with a precision of 1 day. Considering the apparent similarity of the temporal evolution of the velocity change, GPS position, and tremor activity at depth, Brenguier et al. (2008b) proposed that the velocity change is not only related to the well-documented nonlinear response of the shallow layers to strong motion. Wegler et al. (2009) reached a similar conclusion on the existence of a change at depth for the sudden drop in velocity observed after the 2004 Mw 6.6 mid-Niigata earthquake in Japan. Chen et al. (2010) and Froment et al. (2013) studied the case of the 2008 Mw 7.9 Wenchuan earthquake, and they also found a velocity drop associated with the earthquake. They used broadband ambient-noise records and performed the measurements in the two separate period bands of 1–3 s and 12–20 s. The amplitude of the velocity drop was larger for the long-period band. As the measurements are performed with coda waves, they have the depth sensitivity of the predominant surface waves. The results therefore suggest that the change occurs also at depth and affects the middle crust. Furthermore, whether the temporal velocity change is related to deformation at depth can be investigated in the case of slow-slip events that produce significant deformation at depth without strong ground motion at the surface. Rivet et al (2011) found a transient change in the velocity at depth associated

with a large (Mw 7.5) slow-slip event on the Mexican subduction.

Despite promising evidence for the feasibility of monitoring deformation at depth with seismic ambient noise, it is noticeable that the origin of the changes can be obscured by the coincidence of signals of tectonic and hydrological origins (e.g., Froment et al., 2013; Yu and Hung, 2012).

1.12.8 Conclusions

Ambient-noise correlation is emerging as a new tool in seismic data processing. It is complementary to the traditional use of earthquake or active source records. The correlation of ambient-noise records at distant points can be regarded, under certain conditions, as the virtual seismogram recorded at one point if a source was acting at the other.

Physical representations have been provided that allow the reader to have an intuitive understanding of the method. The emergence of the Green's function in cross-correlation is the expression of the fundamental properties of wave fields. This is illustrated by the analogy with time-reversal mirrors that have shown the reconstruction of converging and diverging Green's functions in laboratory experiments. A geometrical interpretation has also been presented that shows that source averaging tends to select the contribution of sources located in the end-fire lobes. Mathematical results have been presented that show that the construction of virtual seismograms is rigorous, and that the complete deterministic response of Earth can be extracted from the records at distant points.

In practice, the ambient noise is produced by sources that are unevenly distributed. In general, this results in incomplete or improper reconstruction. We have analyzed the impact of a nonisotropic distribution of incident noise intensity on the travel times measured on correlations. There is bias, but it is accurately predictable, meaning that corrections can be applied when necessary. With realistic distributions, the method is robust and the bias in the travel time is acceptable for most imaging applications.

The presence of scattering because of the heterogeneous nature of Earth results in complexity of the seismic wave field. As this complexity tends to spread the wave energy over a wide range of directions and to enhance the conversion between the types of waves, it also has a positive role for the correlation of noise. For long lapse times, the field becomes diffuse, having in itself the properties sufficient to obtain the Green's function by correlation. Theoretically, a single source would be sufficient to produce an equipartition field, with its two-point average correlation being the Green's function. This can be understood by considering the scatterers as secondary sources that are uniformly distributed in the medium. With actual normalized noise records, the ballistic waves produced by noise sources are supplemented by the scattered waves of Earth's heterogeneity.

The relatively easy extraction of surface waves by the correlation of noise records has made it possible to apply ambient surface tomography in different places around the world. With this technique, high-resolution crustal models have been proposed, including for shear-wave velocity, anisotropy, and attenuation. Applications have been realized at different scales. Based on the general mathematical properties discussed in Section 1.12.4, and the observation of a teleseismic body-wave component in the noise records, the reconstruction of body waves is expected and has been confirmed by recent studies. This opens the way to the generalization of ambient-noise tomography to all types of waves, including deep phases.

As ambient-noise cross-correlation can be repeated at different dates, these cross-correlations can be used to monitor slight changes in the elastic properties of the crust. The late part of correlations, corresponding to the coda waves, computed at different dates are very stable and allow for the measuring of slight relative changes in seismic speeds, as small as 10^{-4}. Changes in seismic velocity have been observed after large earthquakes, including slow-slip events, in several studies. Velocity drops have been proposed to be precursories of volcanic eruptions and landslides.

The exploitation of ambient seismic noise is an emerging field. The huge data sets produced nowadays by dense permanent and temporary networks offer new opportunities for the development of innovative techniques to construct virtual seismograms that correspond to paths in regions of the planet that are poorly covered. Ambient-noise analysis will continue to provide new insights into the structure of Earth and into its continuous evolution.

1.13.1 Introduction

Mid-ocean ridges mark the boundaries where oceanic plates separate from one another (Figure 1) and thus lie above upwelling regions of mantle circulation. The upwelling mantle undergoes pressure-release partial melting because the temperature of the mantle solidus decreases with decreasing pressure. The melt, being less viscous and less dense than the surrounding solid, segregates from the solid mantle and buoyantly rises to the surface, where it forms new, principally basaltic, oceanic crust. The crust and mantle cool at the surface by thermal conduction and hydrothermal circulation, which generates a strong thermal boundary layer, the lithosphere. As the lithosphere travels away from the ridge, it thickens via additional cooling, becomes denser, and subsides deeper into the underlying ductile asthenosphere. This aging process causes the oceans to double in depth toward continental margins and subduction zones. Mid-ocean ridges represent one of the most important geologic processes shaping the Earth: Over the last 200 million years, two-thirds of the Earth has been resurfaced through this process of seafloor spreading, either at conventional mid-ocean ridge spreading centers or at spreading centers in back-arc basins behind subduction zones; they are a primary means of geochemical differentiation in the Earth; and they drive vast hydrothermal systems that influence ocean water chemistry and support enormous ecosystems.

Around the global ridge system, new crust and lithosphere form along 55 000 total kilometers of ridge at rates that differ by more than a factor of 10 (Figures 1 and 2). This causes large differences in the nature of the magmatic, tectonic, and hydrothermal processes occurring along these ridges. For example, fast-spreading ridges, such as the East Pacific Rise (EPR), exhibit smooth topographic rises with more uniform magmatism, whereas slowly spreading ridges, such as the Mid-Atlantic Ridge (MAR) and Southwest Indian Ridge (SWIR), exhibit heavily faulted deep axial valleys and large variations in volcanic output with time and space. Such observations can be largely understood in the context of two basic processes: asthenospheric flow, which controls temperatures and melt production rates, and the balance between heat delivered to the ridge axis from below and heat extracted by conduction and hydrothermal circulation from above. Additional influences include global variations in mantle background temperature and volatile content, such as near hot spots. In back-arc settings, subducted lithosphere releases water and other elements into the mantle wedge above the subducted plate and below back-arc spreading centers. Consequently, as the back-arc spreading centers open over time, they sweep across strongly varying mantle compositional domains. This influences the degree of melting and the ultimate composition of the crust.

1.13.2 Mantle Upwelling and Melting Beneath Oceanic Spreading Centers

One of the early geodynamic questions about mid-ocean ridges was whether the upwelling is passive, driven simply by the viscous drag of separating plates, or active, a buoyantly rising limb of a convection cell. If global mantle convection is driven largely by cooling from above, then the downwelling limb of convection, in the form of sinking lithospheric slabs, is expected to be cooler than its surroundings and to extend deep into the mantle. If driven by heating from below, as from heat released from the core, then there should also be hot,

 http://dx.doi.org/10.1016/B978-0-444-53802-4.00011-7

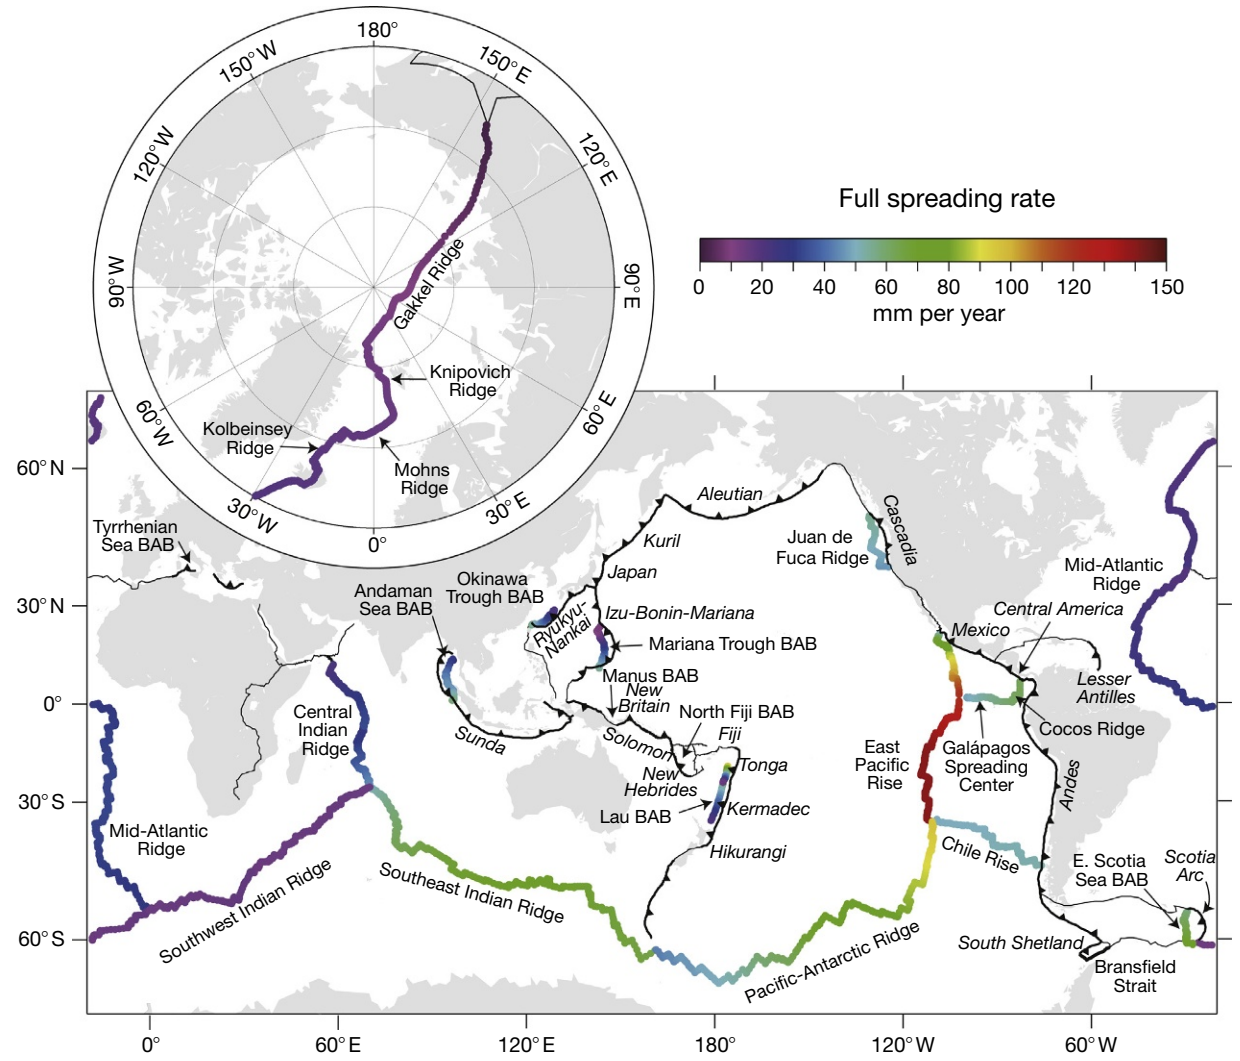

Figure 1 Mid-ocean ridges, active back-arc basins (BABs), and subduction zones of the world. Plate boundaries are from Bird (2003). Spreading rates along the mid-ocean ridges and back-arc spreading centers are calculated from Argus et al. (2011).

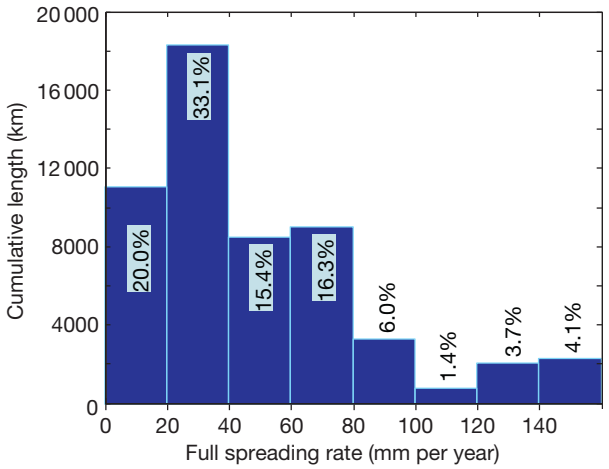

Figure 2 Cumulative length of spreading centers as a function of spreading rate. The percentage of the total length of all ridges (55 400 km) is indicated for each bin. Ridge lengths are calculated using the plate boundary model of Bird (2003) after removal of transform offsets. Spreading rates are calculated from Argus et al. (2011).

upwelling limbs rising from deep in the mantle. There are now a variety of geologic observations that favor dominantly passive mid-ocean ridges, such as the relatively uniform thickness and composition of the oceanic crust. Additionally, seismological studies have clearly shown that there are no deep low-velocity roots beneath typical spreading centers that could correspond to hot buoyant upwellings.

1.13.2.1 Depth Extent of Anomalous Structure

In the mantle, seismic wave velocity and attenuation (energy loss during wave travel) depend on mineralogy, pressure, temperature, and the presence of melt and volatiles; in the upper mantle, lateral velocity and attenuation changes are most often attributed to only temperature and/or melt. Global and large regional seismic studies find anomalously low seismic velocities (e.g., Conley and Dunn, 2011; Gu et al., 2005b; Maggi et al., 2006a,b; Nishimura and Forsyth, 1989; Weeraratne et al., 2007) and high attenuation (e.g., Dalton et al., 2008; Romanowicz, 1994) beneath mid-ocean ridges in the upper mantle, as compared to values at the same depth beneath

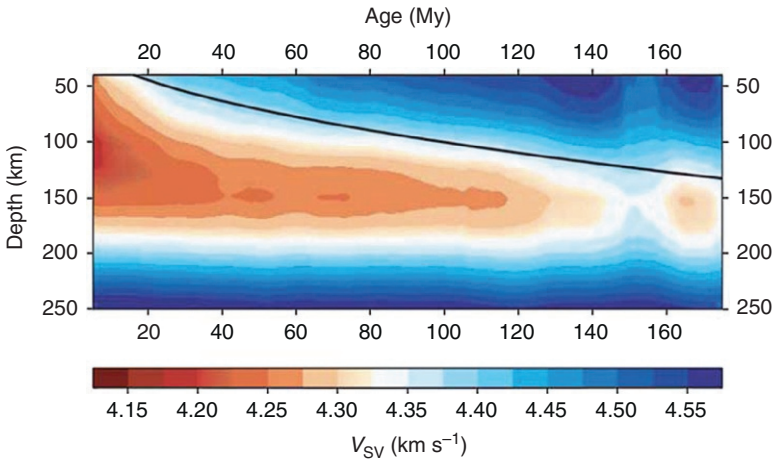

Figure 3 Average shear velocity in the upper mantle as a function of age of the seafloor in the Pacific, based on Rayleigh wave tomography. This smoothed image was generated by averaging over 10 Ma sliding age windows. The black line indicates the base of the lithosphere predicted for a cooling half-space thermal model. Reproduced from Maggi A, Debayle E, Priestley K, and Barruol G (2006a) Multimode surface waveform tomography of the Pacific Ocean: A closer look at the lithospheric cooling signature. *Geophysical Journal International* 166: 1384–1397.

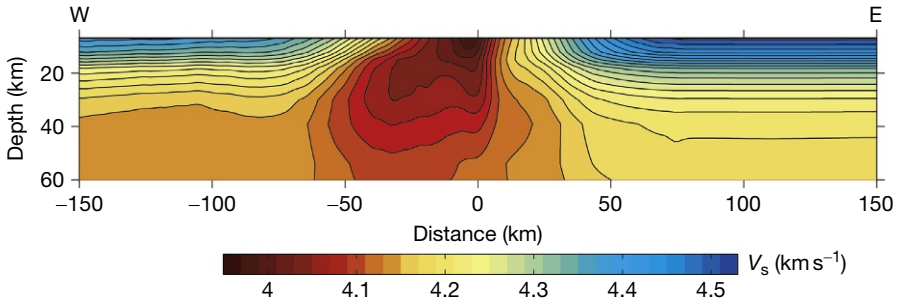

Figure 4 Short-period Love wave image of the upper mantle beneath the southern East Pacific Rise (reproduced from Dunn RA and Forsyth DW (2003) Imaging the transition between the region of mantle melt generation and the crustal magma chamber beneath the southern East Pacific Rise with short-period Love waves. *Journal of Geophysical Research* 108(B7): 2352. http://dx.doi.org/10.1029/2002JB002217). A broad asymmetric low SH-wave anomaly occurs beneath the ridge that is flanked by high lithospheric velocities at shallow depths. The lowest velocities (<4 km s^{-1}) occur just beneath the base of the crust (top of the figure).

older seafloor (**Figure 3**). The lateral velocity contrasts can largely be explained by an increase in the thickness of the thermal boundary layer, or lithosphere, with age, but beneath the ridges, the velocities are sufficiently low to imply the presence of a small amount of melt in the asthenosphere. Minimum isotropic shear-wave velocities, ~4 km s^{-1}, are often found between 40 and 80 km depth. However, regional seismic studies using relatively short-period surface waves, which provide increased depth resolution of the upper ~60 km, indicate that the velocity minimum is shallower and more pronounced directly beneath ridges, where melts might aggregate as they rise toward the surface (**Figure 4**; Conley and Dunn, 2011; Dunn and Forsyth, 2003).

Beneath mid-ocean ridges, the anomalous velocity structure appears to extend no deeper than about 200 km. There are several lines of evidence. The thickness of the mantle transition zone, located between seismic discontinuities at 410 and 660 km depth, is one indicator of upper mantle temperature, because the two discontinuities are governed by phase changes with Clapeyron slopes of opposite sign. Global maps of the topography of these discontinuities, based on precursors to SS seismic phases resulting from underside reflections (SdS phases), show a correlation of greater transition zone thickness with the location of subduction zones, indicating colder temperatures in the vicinity of descending slabs. However, there is no correlation of transition zone thickness with mid-ocean ridges (Flanagan and Shearer, 1998; Lee and Grand, 1996; Shearer, 2000). A local study of P-to-SV conversions at these discontinuities beneath the EPR, using receiver function analysis of data recorded on an array of ocean-bottom seismographs, found that the time difference between the P410s and the P660s conversions is almost exactly equal to the global average (Shen et al., 1998), indicating that any thermal anomaly is confined to the upper mantle above the 410 km discontinuity. A study of multiple S phases in the vicinity of the EPR also found no vertical displacement of either the 410 or the 660 km discontinuities (Melbourne and Helmberger, 2002).

Global and regional tomographic studies based on body-wave travel times sometimes show mid-ocean ridge structure extending down to depths of 300–400 km (Masters et al., 2000), but because ray paths in the upper mantle are relatively steep, there typically is a trade-off between the amplitude of the

anomaly and its depth extent. In the inversion of travel times to obtain velocity structure, if velocity variations are damped to prevent unrealistic oscillations, then the tendency is to force the model to smear large-amplitude shallow anomalies beyond their actual depth extent. In one body-wave study, using an array of seafloor seismographs that crossed the EPR (Hammond and Toomey, 2003), a 'squeezing' test was performed in which model anomalies were progressively limited to shallower depths. The variation in quality of data fit showed that the anomalous structure extends to no more than 200–300 km depth. Rayleigh waves with periods in the range ~15–160 s have the best sensitivity to the depth distribution of shallow mantle velocities. Global or regional tomographic models based on Rayleigh surface waves or surface and body waves combined (Conley and Dunn, 2011; Ekström, 2000; Maggi et al., 2006a; Masters et al., 2000; Nishimura and Forsyth, 1989; Priestley and McKenzie, 2006; Ritsema, 2005; Ritzwoller et al., 2004; Zhou et al., 2006) find that the anomalous structure in the vicinity of most ridges is confined to the uppermost 150–200 km of the mantle (**Figure 3**), except perhaps in the vicinity of a large hot spot like Iceland (**Figure 5**).

1.13.2.2 The Onset of Melting

If low velocities beneath the ridges indicate the presence of melt, then the bottom of the low-velocity zone should indicate the onset of melting at the solidus. However, the bottom is more difficult to define than the top because the resolution of surface waves decreases with increasing depth and the transition may be subtle if the initial melt fraction is very small. In addition, seismic velocities naturally increase with increasing depth and pressure even away from mid-ocean ridges. Beneath the point of minimum asthenospheric velocity, velocities increase rapidly with depth, though the velocity gradient decreases between ~100 and 150 km depth (e.g., Gu et al., 2005b; Maggi et al., 2006a; Nishimura and Forsyth, 1989; Weeraratne et al., 2007). This change in gradient may correspond to the solidus.

One interpretation of the seismological observations that is consistent with experiments on the melting of peridotite and observations of electrical conductivity structure near the EPR (Evans et al., 2005; Key et al., 2013) is that melting begins in the upwelling mantle in the presence of a small amount of water dissolved in the solid crystals at depths of 100–150 km.

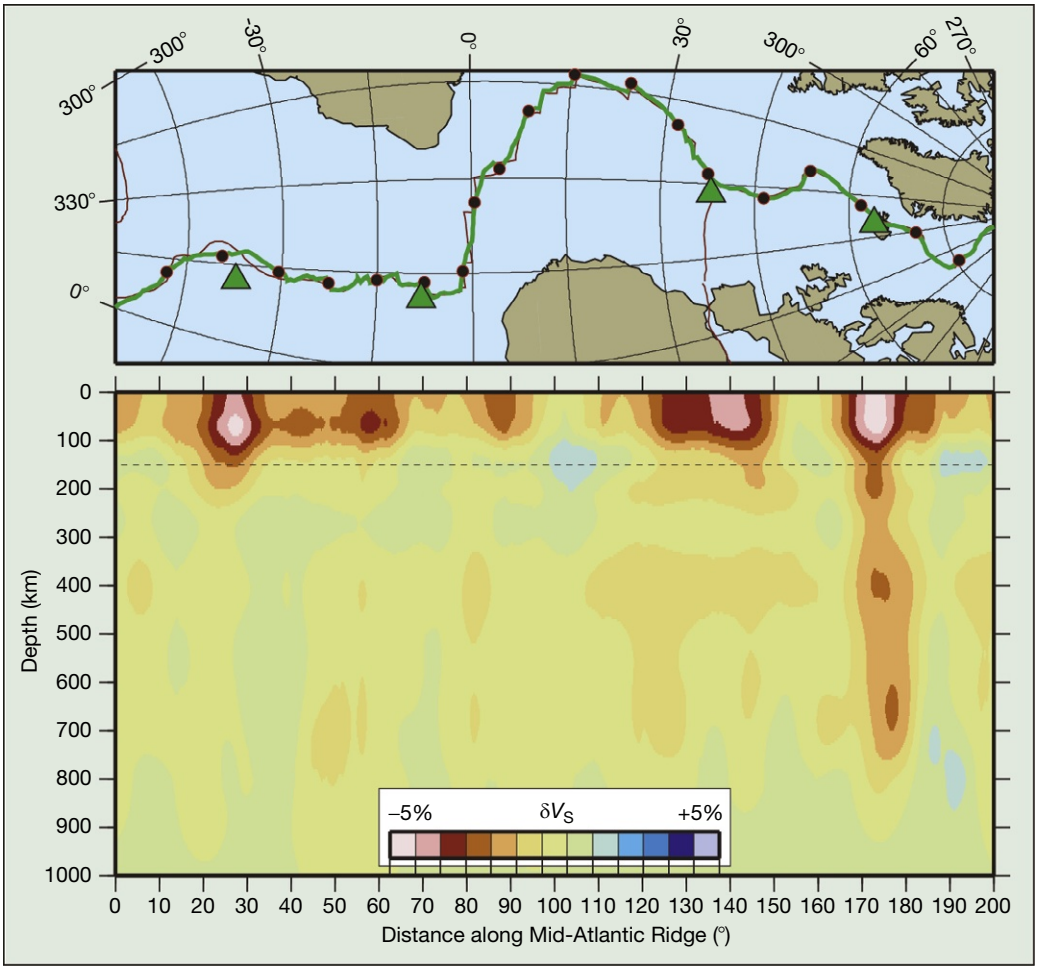

Figure 5 Mantle S-wave velocity structure beneath the Mid-Atlantic Ridge and neighboring hot spots. (Bottom) Shear-wave profile along the ridge relative to the global average. (Top) Green line indicates location of the profile; circles occur at 10° intervals. Green triangles indicate hot spot locations. Anomalous structure is largely limited to depths <150 km (dashed line) except beneath Iceland. Reproduced from Montagner J-P and Ritsema J (2001) Interactions between ridges and plumes. *Science* 294: 1472–1473.

The melt concentration gradually increases upward as melting proceeds above the damp solidus, but melt concentration and total degree of melting remain small below the dry solidus. Water behaves like an incompatible element and tends to concentrate in the melt, so as melting proceeds, the matrix dehydrates. Around 60–80 km depth, the rate of melting increases as the dry solidus is passed, but the additional melt migrates upward toward the ridge axis leaving only a small (less than ~1%) melt fraction and a dehydrated matrix behind.

1.13.2.3 Mantle Flow near Ridges

Seismic anisotropy offers clues to the form of mantle flow beneath mid-ocean ridges. Observations of seismic anisotropy in the upper mantle are often attributed to a strain-induced lattice-preferred orientation of olivine that occurs during mantle flow. Olivine is elastically anisotropic and the general alignment of the 'fast' *a*-axis of olivine grains results in detectable seismic anisotropy. From a seismic detection standpoint, two basic forms of anisotropy have been identified. One is radial anisotropy (SV$\neq$SH), also called transverse isotropy, which is typically detected via a discrepancy between Love and Rayleigh wave phase velocities relative to an isotropic model. (Love waves are sensitive to horizontally propagating, horizontally polarized S-wave speeds, or SH, while Rayleigh waves are sensitive to horizontally propagating, vertically polarized S-wave speeds, or SV.) The other is azimuthal anisotropy, which is detected by an azimuthal variation in body-wave travel times and surface-wave phase velocities, and via shear-wave splitting.

A characteristic found consistently in global and large-scale regional models of oceanic mantle structure is radial anisotropy down to about 250 km depth. Below oceanic lithosphere, SH generally exceeds SV by a few percent (Kustowski et al., 2008; Nishimura and Forsyth, 1989; Shapiro and Ritzwoller, 2002), a pattern expected for horizontal flow. Near mid-ocean ridges, surface-wave studies detect azimuthal anisotropy in the uppermost mantle with the fast direction for the propagation of Rayleigh waves approximately in the spreading direction, as predicted for the deformation associated with upwelling and subsequent plate separation at spreading centers (Blackman and Kendall, 1997; Forsyth, 1975; Maggi et al., 2006b; Montagner and Tanimoto, 1991; Ritzwoller et al., 2004) that aligns the olivine *a*-axis horizontally in a direction perpendicular to the ridge.

At shallow depths within the lithosphere and low-velocity zone, regional tomographic studies have reported a reduction in radial anisotropy in young seafloor near the EPR, although SH is still faster than SV. Along the southern EPR, azimuthal anisotropy of short-period Rayleigh waves reaches a minimum at the ridge axis (Forsyth et al., 1998), consistent with either a component of vertical upwelling or not yet established horizontal flow. In that area, the smallest shear-wave splitting delays were also found immediately adjacent to the axis, but the most pronounced pattern in the splitting data is an asymmetry in splitting delays across the ridge; the fast direction is roughly perpendicular to the ridge on both sides, but splitting delays are nearly twice as large on the Pacific plate as on the Nazca plate (Wolfe and Solomon, 1998). This asymmetry may be an indicator of asymmetric asthenospheric flow toward the ridge, although Harmon et al. (2004) have shown that splitting times decrease in older Pacific seafloor to levels near that of the Nazca plate. Hammond and Toomey (2003) found that there may be a region of tilted olivine alignment responsible for some of the pattern of P and S delays near the ridge, but it is not clear that there is any region of dominantly vertical alignment of the olivine *a*-axis beneath the EPR at depths shallower than 200 km.

The mantle velocity structure beneath the southern EPR is also asymmetric. At depths of a few tens of kilometers, the slowest velocities are west of the axis (Forsyth et al, 1998; Hammond and Toomey, 2003; Harmon et al., 2009) and slower average velocities in the upper 60 km persist for hundreds of kilometers from the axis (**Figure 6(a)**). Global attenuation models also show an asymmetry, with higher seismic attenuation to the west than to the east (Romanowicz, 1994). Although crustal structure seems to be symmetric, short-period Love waves (3–15 s) indicate that the velocity asymmetry begins just beneath the Moho (**Figure 4**; Dunn and Forsyth, 2003). On the eastern, Nazca plate side of the ridge, there are increases in velocity down to depths of 60 km or more within 50 km of the ridge axis, changes penetrating much deeper into the mantle than expected from conductive cooling of the plate alone (Conder et al., 2002). Accompanying the asymmetry in seismic velocities is an asymmetry in subsidence of the seafloor, with anomalously slow subsidence on the Pacific plate side of the ridge (Cochran, 1986; Scheirer et al., 1998). This pattern indicates that there is asthenospheric flow toward the ridge from beneath the Pacific plate, accompanied perhaps by flow across the axis that is deflected downward beneath the thickening Nazca plate, rapidly eliminating any melt fraction in the residual mantle to the east of the ridge (**Figure 6(b)**; Conder et al., 2002; Toomey et al., 2002). Flow from the Pacific side is thought to be anomalously warm and perhaps anomalously enriched and may arise from the South Pacific Superswell region thousands of kilometers to the west. Panza et al. (2010) argue that asymmetric mantle structure exists beneath migrating mid-ocean ridges across the globe.

From the available evidence just described, it appears that the low-velocity zone beneath the ridges may correspond to a low-viscosity asthenosphere dominated by horizontal flow and shear between the overriding plate and the underlying deeper mantle (**Figure 6(b)**; Conder et al., 2002). In contrast, global studies employing Love waves sometimes report anomalies extending deeply beneath spreading centers (**Figure 7**; Gu et al., 2005a; Gung et al., 2003; Zhou et al., 2006), as compared to tomographic images with Rayleigh waves, which have much better vertical resolution. Vertical smearing due to poor Love wave resolution could be responsible for this discrepancy, but synthetic tests suggest that the difference is real, indicating that radial anisotropy reverses from the usual SH > SV pattern in shallow oceanic mantle to SH < SV at depths > 200 km beneath mid-ocean ridges. This may indicate deep vertical upwelling to depths on the order of 300 km (Gu et al., 2005a; Zhou et al., 2006), rather than a more horizontal flow in the asthenosphere that feeds mantle material to ridges (Conder et al., 2002). The absence of an accompanying Rayleigh wave anomaly, or a deflection of the 410 km discontinuity, indicates that any such deep upwelling is probably passively induced with no accompanying thermal anomaly.

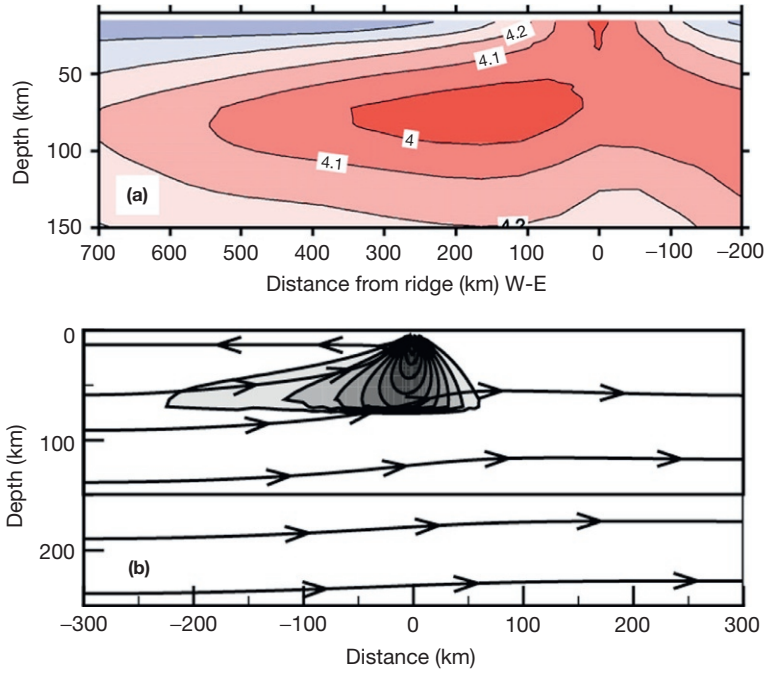

Figure 6 (a) The shear-wave velocity model of the southern East Pacific Rise. Cool colors correspond with lithospheric velocities and warm colors with asthenospheric velocities (reproduced from Harmon N, Forsyth DW, and Weeraratne DS (2009) Thickening of young Pacific lithosphere from high-resolution Rayleigh wave tomography: A test of the conductive cooling model. *Earth and Planetary Science Letters* 278: 96–106). (b) The mantle flow model with an across-ridge pressure gradient that drives asymmetric flow across the ridge (reproduced from Conder JA, Forsyth DW, and Parmentier EM (2002) Asthenospheric flow and the asymmetry of the East Pacific Rise, MELT area. *Journal of Geophysical Research* 107(B12): 2344. http://dx.doi.org/1029/2001JB000807). Note that the scale differs between the top and the bottom plots.

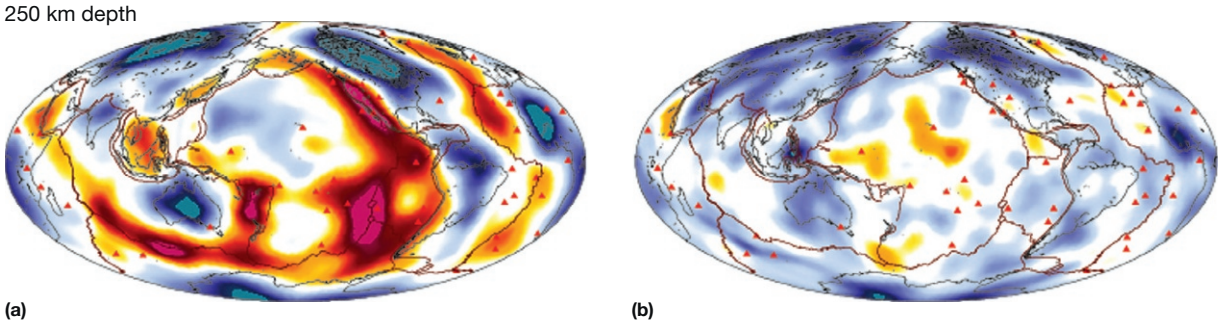

Figure 7 Shear-wave velocity anomalies at a depth of 250 km from Love waves (a) and Rayleigh waves (b). Plate boundaries are indicated by brown lines, and hot spots by red triangles. Note that there are low velocities along most of the mid-ocean ridges in the Love wave image (SH velocity), but there are no such anomalies for Rayleigh waves at this depth. This discrepancy is due to either seismic anisotropy or greater vertical smearing of the SH velocity anomalies. Reproduced from Zhou Y, Nolet G, Dahlen FA, and Laske G (2006) Global upper-mantle structure from finite-frequency surface-wave tomography. *Journal of Geophysical Research* 111: B04304. http://dx.doi.org/10.1029/2005JB003677.

1.13.2.4 Passive Versus Buoyant Upwelling

Although the overall upwelling beneath mid-ocean ridges appears to be passively driven by plate motions, it is possible that when decompression melting begins, enough low-density melt is retained in the mantle matrix to create local buoyancy and local, small-scale convection beneath the ridge. Any reduction in effective viscosity due to melt retention could lead to enhanced and concentrated upwelling into narrow sheets beneath the spreading center or into a 3D pattern of melt-rich diapirs. The concentration of upwelling into a narrow zone is one possible explanation of a major puzzle posed by the conclusion that overall upwelling is passive. The problem is that passive upwelling is expected to be broad; when rising mantle ascends above the solidus, melting thereby occurs over a region that may be >100 km across. Within the mantle matrix, melt buoyancy tends to drive melt vertically, yet seismic reflection profiles indicate that the crust is fully formed within 1–2 km of the ridge axis (Detrick et al., 1987; Singh et al., 2006b) and not over a >100 km region. In addition, surveys of off-axis volcanism in the form of seamounts and lava flows indicate that more than 98% of the basaltic crust is formed at the ridge axis (Shen et al., 1993). Buoyancy of the entire mantle

matrix due to the presence of melt could explain these observations by focusing the upwelling to the ridge axis. If melt production is not concentrated beneath the ridge axis by focused upwelling, then there must be some other mechanism to guide or force the melt produced in a broad region to the ridge axis. Suggestions include nonvertical pressure gradients associated with deformation of a highly viscous mantle, anisotropic permeability, and formation of sloping, melt-rich, high-permeability channels at a freezing front at the base of the lithosphere (Phipps Morgan, 1987; Sparks and Parmentier, 1991; Spiegelman and McKenzie, 1987).

To distinguish between models of broad and narrow upwelling at the end-member case of a high-spreading-rate ridge, the MELT seismic experiment was carried out across the fast-spreading southern EPR (MELT Seismic Team, 1998). This part of the EPR is unusually linear, with no offsets, in the form of transform faults or overlapping spreading centers (OSCs) >5 km, over a distance along the ridge of several hundred kilometers. Both body- and surface-wave tomography revealed a broad region of low velocities, interpreted to be the region of melt production (Forsyth et al, 1998; Hammond and Toomey, 2003; Harmon et al., 2009). There was no indication of a narrow zone of very low velocities that would be expected if enough melt was present to lower the viscosity and increase the buoyancy enough to concentrate upwelling into a narrow zone. It is possible that if the zone were narrow enough, it could have escaped detection, but the waveforms of teleseismic body waves passing directly through the shallow upper mantle beneath the ridge place strict limits on the product of the amplitude of the velocity anomaly and width of the low-velocity channel (Hung et al., 2000).

There is some seismic evidence for three-dimensional (3D) flow or melting in a variety of settings, including in the MELT study area. Combining surface-wave data from the MELT and adjacent GLIMPSE experiments, Harmon et al. (2007, 2011) report two minima in shear-wave velocity along the EPR: one where the Sojourn and Brown intraplate ridge and seamount system intersect the spreading center at ~14° S and the other at the beginning of the Rano Rahi seamount field at ~17–18° S (**Figure 8**). The low-velocity anomalies presumably indicate higher temperatures and/or higher melt concentrations. The association of these two minima with the formation of off-axis seamounts and a geochemical anomaly at 17° S suggests that the 3D character is controlled by the influx of anomalous mantle to the ridge, rather than an inherent instability that leads to a breakdown of the 2D upwelling pattern.

Evidence for 3D flow is also found in the Gulf of California, where a complex ridge system is composed of short sections of spreading ridge that are often offset by long fracture zones. A model invoking passive mantle upwelling would predict anomalously slow wave speeds beneath these spreading segments, but Wang et al. (2009) found punctuated shear velocity anomalies in the mantle that are offset by tens to hundreds of kilometers from the spreading segments. The authors interpret these results as evidence of complex buoyancy-driven mantle upwelling. At a depth just beneath the base of the oceanic crust, three-dimensionality is also observed in the mantle beneath the fast-spreading northern EPR and slow-spreading MAR (see **Section 1.13.3**). Active-source refraction experiments have mapped along-axis variations in P-wave velocity, with

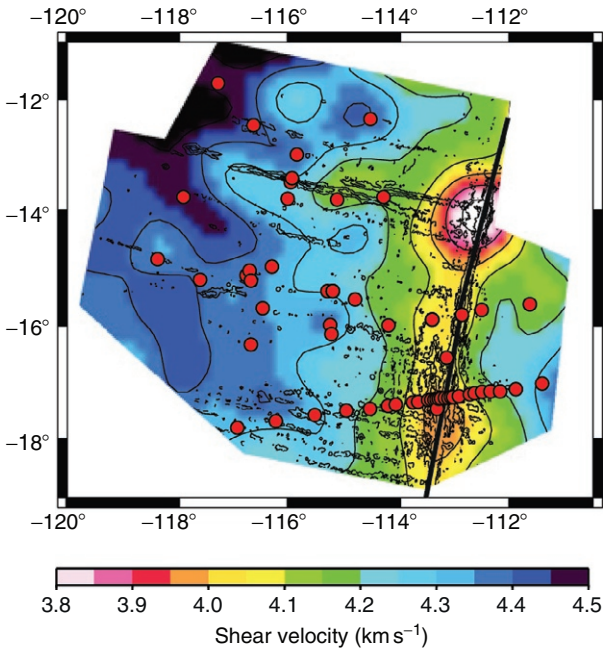

Figure 8 Map of shear-wave velocities near the southern East Pacific Rise (average over 10–45 km depth). The axis of the ridge (straight black lines) runs roughly north–south along the eastern side of the image. Two anomalies along the ridge suggest 3D upwelling and/or melting. Red circles are seismograph positions. A 1000 m water depth contour highlights locations of volcanic edifices. Reproduced from Harmon N, Forsyth DW, Weeraratne DS, Yang Y, and Webb SC (2011) Mantle heterogeneity and off axis volcanism on young Pacific lithosphere. *Earth and Planetary Science Letters* 311: 306–315.

quasiperiodic low-velocity anomalies beneath the EPR (Dunn et al., 2000; Toomey et al., 2007) and with one single low-velocity anomaly beneath an MAR segment (Dunn et al., 2005). One idea is that these anomalies represent the tops of centers of mantle upwelling, although their depth extent is not known and it is possible that they are centers of melt migration and accumulation rather than centers of upwelling of the solid mantle.

1.13.2.5 Spreading Rate Dependence

Mid-ocean ridge morphology and crustal formation are known to depend on the spreading rate of the ridge: as spreading rate decreases along the global mid-ocean ridge system, the average depth of ridge axes becomes greater and more variable, more segmented, and more heavily rifted. Along individual ridge segments, their morphological character increases in complexity and crustal formation becomes more 3D and time-varying as spreading rate drops. While the fastest-spreading ridges (with opening rates >90 mm year^{-1}) exhibit broad axial highs, long straight segments of ridge, and relatively uniform crustal thickness, slower-spreading ridges (20–60 mm year^{-1}) exhibit deep axial valleys within ridge segments that have an overall hourglass shape and variable crustal thickness. At ultra-slow spreading rates (<20 mm year^{-1}), ridge axes are composed of en echelon linked magmatic and amagmatic segments that often display asymmetric spreading across the

ridge, and the general spreading direction is often oblique to the trend of the ridge, rather than perpendicular (Cannat et al., 2006; Dick et al., 2003). These changes in ridge axis character are probably associated with the basic rheology of the ridge axis and its spreading rate dependence. As the spreading rate drops, cooling from above becomes relatively more important than heat delivery from below and the effective thickness of the lithosphere increases; in addition, the depth interval of seismicity and the depth to which crustal magma chambers can be found increase (**Figure 9**) and become more variable. Early modeling studies of ridge dynamics (Chen and Morgan, 1990a,b; Phipps Morgan and Chen, 1993a,b) support the idea that ridge axis morphology is a direct consequence of the thickness of the axial lithosphere.

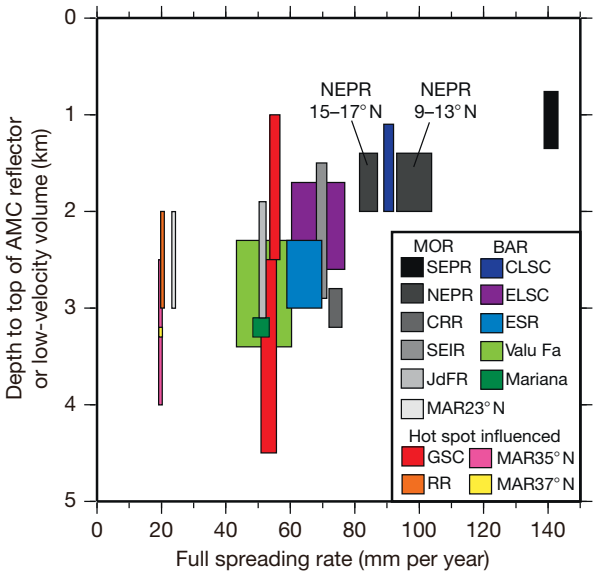

Figure 9 Depth to the axial magma chamber (AMC) or to the top of the axial low-velocity volume, as a function of spreading rate. Note that at slower spreading rates, there is a large observational bias in the trend: beneath many ridge segments with intermediate to slow spreading rates, no evidence for a magmatic system can be found. SEPR, south East Pacific Rise (Detrick et al., 1993; Hooft et al., 1997; Kent et al., 1994; Mutter et al., 1995; Singh et al., 1998, 1999; Tolstoy et al., 1997); NEPR, north East Pacific Rise (Burnett et al., 1989; Canales et al., 2012; Carbotte et al., 1998, 2000, 2012; Collier and Singh, 1997; Detrick et al., 1987; Dunn et al., 2000; Durant and Toomey, 2009; Harding et al., 1993; Kent et al., 1993; Toomey et al., 1994; Vera et al., 1990; Vera and Diebold, 1994); CRR, Costa Rica Rift (Buck et al., 1997; Mutter, 1995); SEIR, Southeast Indian Ridge (Baran et al., 2005); JdFR, Juan de Fuca Ridge (Canales et al., 2005, 2006; Carbotte et al., 2006, 2008; Christeson et al., 2010; Menke et al., 2002; Morton et al., 1987; van Ark et al., 2007); MAR, Mid-Atlantic Ridge (Canales et al., 2000a,b; Dunn et al., 2005; Seher et al., 2010a,b; Singh et al., 2006a,b); CLSC, Central Lau Spreading Center (Jacobs et al., 2007); ELSC, Eastern Lau Spreading Center (Dunn et al., 2013; Jacobs et al., 2007); ESR, East Scotia Ridge (Bruguier and Livermore, 2001; Livermore et al., 1997); Valu Fa Ridge (Collier and Sinha, 1990, 1992; Jacobs et al., 2007; Turner et al., 1999); Mariana Trough (Becker et al., 2010); GSC, Galápagos Spreading Center (Blacic et al., 2004; Detrick et al., 2002); RR, Reykjanes Ridge (Navin et al., 1998; Peirce et al., 2007; Sinha et al., 1998). Spreading rate of CRR is from Hey et al. (1977). Other spreading rates are calculated from Argus et al. (2011).

While long straight segments of fast-spreading mid-ocean ridge may be predominantly underlain by upwelling and melting that is more 2D in form, along the axes of slow-spreading ridges, the supply of melt from the mantle is widely considered to be highly variable, both spatially and temporally. For ridge segments bounded by large tectonic offsets, the midsections often exhibit the shallowest bathymetry and thickest crust, while the segment ends exhibit wide, deep axial valleys and thin crust, as deduced from gravity (Detrick et al., 1995; Kuo and Forsyth, 1988; Lin et al., 1990) and seismic data (Canales et al., 2000b; Dannowski et al., 2011; Dunn et al., 2005; Hooft et al., 2000; Hosford et al., 2001; Purdy and Detrick, 1986; Sinha and Louden, 1983; Tolstoy et al., 1993). Although these observations can be explained by a number of mantle geodynamic scenarios, each one predicts that melt flux is focused at mantle depths and delivered to a segment's center (e.g., Kuo and Forsyth, 1988; Lin et al., 1990; Magde et al., 1997; Rabinowicz et al., 1993; Sparks et al., 1993; Whitehead et al., 1984). Melt focusing may occur due to mantle diapirism or by following the bottom of a freezing front at the base of the lithosphere that shallows near segment centers (Magde et al., 1997). Theoretical studies (Parmentier and Phipps Morgan, 1990) indicate that as spreading rate drops, mantle buoyancy becomes progressively more important relative to viscous drag and upwelling is more likely to break up into a 3D diapiric form. While there is overwhelming evidence for 3D melt supply along slow-spreading ridges, there is as yet no conclusive seismic evidence for buoyant diapiric upwellings of the mantle matrix along slow-spreading ridges; most of what we know about the patterns of upwelling, melt production, and melt flux is inferred from studying the final product, that is, lateral variations in structure and thickness of the oceanic crust accreted at the Earth's surface and not from direct seismic study.

While strong spreading rate correlations exist, it is clear that spreading rate alone cannot account for much of the diversity of the ridge system. Mantle temperature and compositional heterogeneity may also play a role. Langmuir et al. (1992) showed that geographic variation in mantle potential temperature can account for significant differences between sections of ridge. Mantle hot spots are known to significantly affect nearby sections of mid-ocean ridge, producing thicker crust and shallower ridge axes; mantle volatiles in ridge magmas also increase toward hot spots (water acts as a melting flux by lowering the solidus temperature; e.g., Schilling et al., 1980, 1982). Mantle cold spots have also been postulated (Hayes, 1976, 1988; Klein and Langmuir, 1987), such as near the Australian–Antarctic Discordance, along the Southeast Indian Ridge, where seismic images suggest a large-scale high-velocity (cooler) feature in the upper mantle (Ritzwoller et al., 2003). Mantle chemical variations may also influence ridge processes. For example, Warren et al. (2009) infer global variations in mantle source chemistry for ridges on the basis of abyssal peridotite samples, and Zhou and Dick (2013) recently suggested that a previous melting event has left a large region of depleted upper mantle beneath the Marion Rise along the Southwest Indian Ridge.

For $\sim$80% of ridges with spreading rates $>$20 mm year^{-1}, melt production appears to be independent of spreading rate. Faster-spreading ridges produce roughly the same

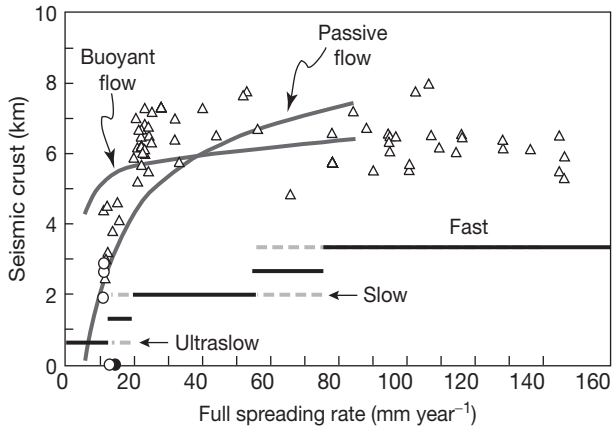

Figure 10 Global distribution of crustal thickness as a function of spreading rate. Triangles are seismically determined crustal thickness estimates. Crustal thickness drops off quickly as the spreading rate drops below 20 mm year^{-1}. Typical divisions of ridge spreading rate are shown. Gray crustal thickness curves were calculated for passive flow and buoyant flow geodynamic models. Reproduced from Dick HJ, Lin J, and Schouten H (2003) An ultraslow-spreading class of ocean ridge. *Nature* 426: 405–412.

amount of crust, 6–7 km, as slower-spreading ridges. However, crust produced at ridges with spreading rates less than ~20 mm year^{-1} is observed to be <4 km thick, well below the global average for faster rates (**Figure 10**; Coakley and Cochran, 1998; Cochran et al., 2003; Géli et al., 1994; Jokat et al., 2003; Klingelhöfer et al., 2000; Ritzmann et al., 2002). For some sections of these ridges, the melt supply at least temporarily drops to zero, resulting in the direct emplacement of mantle at the seafloor (e.g., Cannat et al., 2006; Dick et al., 2003). This change in crustal production at very slow spreading rates indicates a fundamental change in subridge processes; yet its origin is unknown. At present, there are two end-member hypotheses. While each emphasizes the existence of a cold thermal lid, one speculates that the thermal lid inhibits melting, while the other suggests that it inhibits melt migration.

The former hypothesis predicts that under very slow-spreading conditions, there is efficient, deep cooling of the upper mantle beneath the ridge. At a spreading rate of 10 mm year^{-1}, it takes about 10 million years for a parcel of mantle to rise from the dry solidus to beneath the ridge axis, long enough for the mantle to lose heat by conduction to the surface while it is still rising (Shen and Forsyth, 1995). This presumably allows a thick thermal boundary layer to form that depresses the top of the melting region, thereby shutting off melting much deeper than along faster-spreading ridges (Brown and White, 1994; Niu and Hekinian, 1997; Reid and Jackson, 1981; Shen and Forsyth, 1995). In contrast to fast-spreading ridges, where melting is predicted to continue up to nearly the base of the crust, numerical calculations (Reid and Jackson, 1981) predict that along ultraslow ridges, melting shuts off at a depth of 30 km or more beneath the base of the crust. Although the 'thick lithosphere' concept provides a useful working hypothesis, it does not provide a unique interpretation of available data, nor does it account for the tendency of rising melts to freeze into the mantle, as a consequence of the cool boundary layer, and release heat. In support of this model, samples taken from ultraslow ridges exhibit incompatible element enrichments, indicative of low degrees of melting (Dick et al., 2003; Klingelhöfer et al., 2000; Michael et al., 2003; Robinson et al., 2001), though the amount of melting that occurs along these ridges, as reflected by crustal thickness and enrichment of incompatible elements, does not distinguish control between by conductive cooling and by other factors such as mantle temperature (Klein and Langmuir, 1989; Langmuir et al., 1992) or composition (Robinson et al., 2001).

In the alternative hypothesis, a large proportion of the melt generated beneath the ridge is simply frozen into the uppermost mantle (Cannat, 1996). In this hypothesis, the upper mantle is not cooled to great depth and no deep shutoff point for melting exists. Instead, a thin but strong lithosphere at the uppermost part of the mantle restricts the passage of melt just beneath the ridge. Thus, crustal thickness does not represent the total amount of melting that occurs. In support of this hypothesis, a short-period surface-wave study along the Mohns Ridge found an ~10 km thick region just below the crust of low S-wave velocities (**Figure 11**) (Conley and Dunn, 2011); a seismic refraction experiment in the same area found low subcrustal P-wave velocities (Klingelhöfer et al., 2000); and a seismic refraction study of Atlantic lithosphere found an abrupt drop in subcrustal P-wave velocities correlating with a change from slow to ultraslow paleospreading rate (Lizarralde et al., 2004). In each case, the low velocities suggest the presence of melt frozen into the uppermost mantle, and the estimated volume of retained melt in the mantle balances the amount of 'missing' melt in the crust.

Along ultraslow ridges, crustal thickness does not decrease monotonically with decreasing spreading rate. Instead, large temporal variations in crustal thickness and inferred melt supply exist along the Gakkel Ridge, and this additionally supports a permeability barrier model over a model that favors lower total melting. To some extent, both hypotheses may be correct, and some amount of both deep cooling and melt retention seems likely. If melts freeze into the upper mantle to some degree at all slow- to very slow-spreading ridges, then there may be large reservoirs of unaccounted for gabbroic melt frozen into the mantle throughout many ocean basins.

1.13.2.6 Back-Arc Spreading Centers

A general model for the creation of back-arc basins behind subduction zones proposes that lithospheric extension (via trench rollback or other mechanism) initiates rifting near the volcanic arc, where the lithosphere is expected to be weak, followed by seafloor spreading that eventually develops into well-organized, mid-ocean-ridge-like spreading centers (e.g., Hawkins, 1976; Karig, 1970; Taylor and Karner, 1983). With continued opening of the basin along these ridges, the ridges and volcanic arc separate and the ridges entrain lower and lower degrees of slab-derived water and other elements in their melting regimes (Pearce et al., 1995). Although back-arc spreading centers have many similarities to mid-ocean ridges, they tend to be more complex and often display evidence for rift jumps, spreading center propagation (e.g., Parson et al., 1990), rapid temporal variations in spreading rate (Jurdy and Stefanick, 1983), and large morphological and geochemical

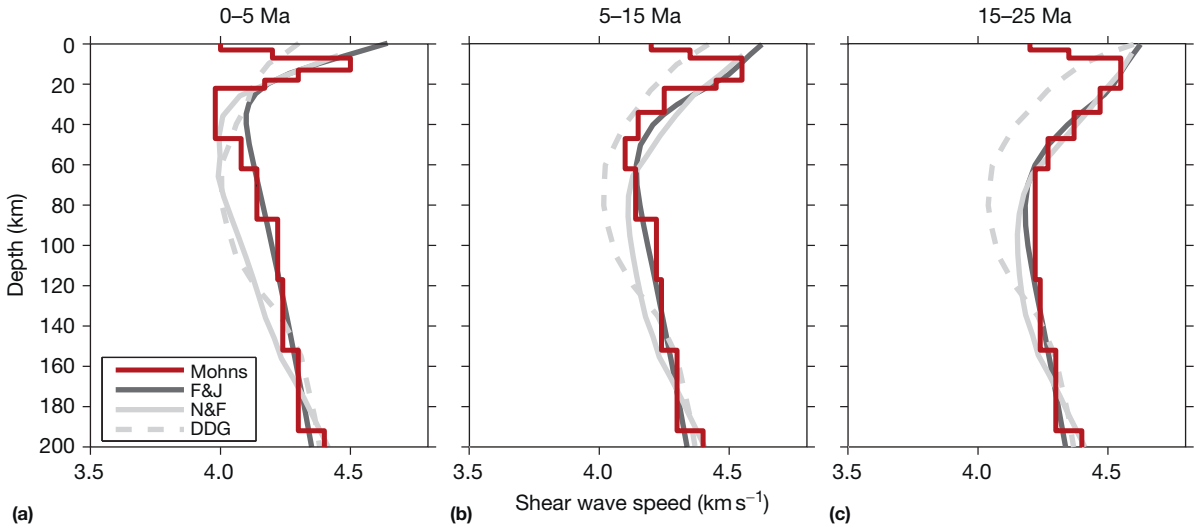

Figure 11 Mohns Ridge SV models as compared to other models for the same age ranges. F&J, a half-space cooling model converted to seismic shear-wave speed via the method of Faul and Jackson (2005); N&F, Pacific mantle model of Nishimura and Forsyth (1989); DDG, the North Atlantic, Reykjanes Ridge, model of Delorey et al. (2007). All models are referenced to the base of the crust. The Mohns model contains a subcrustal low-velocity region in the topmost ~10 km of mantle. Within the 0–5 Ma age range (and larger ranges for the Reykjanes model), the regional models differ from the F&J prediction by having lower sublithospheric shear velocities that may indicate the presence of a small amount of melt in the upper mantle. Reproduced from Conley MM and Dunn RA (2011) Seismic shear wave structure of the uppermost mantle beneath the Mohns Ridge. *Geochemistry Geophysics Geosystems* 12: Q0AK01. http://dx.doi.org/10.1029/2011GC003792.

variations (Taylor and Karner, 1983; Taylor and Martinez, 2003). In recent years, extensive geophysical (e.g., Bruguier and Livermore, 2001; Dunn and Martinez, 2011; Goodliffe et al., 1997; Taylor and Martinez, 2003) and geochemical mapping studies (e.g., Bézos et al., 2009; Escrig et al., 2009; Langmuir et al., 2006; Pearce et al., 2005) have made significant progress toward piecing together these complex systems.

However, relatively little is known about the dynamical processes occurring in the wedge of mantle located above the subducting slab and below back-arc and arc systems; yet within these regions, significant processes controlling the evolution of the Earth occur, for example, the recycling of cold lithosphere back into the deeper mantle, the hydration of the mantle from volatiles released from the slab, and chemical differentiation that accompanies arc and back-arc melting and magmatism. Strong variations in volatile content of the mantle wedge (e.g., Kelley et al., 2006), and the driving influence of the subducting slab on wedge flow (Ribe, 1989; Sleep and Toksöz, 1971), are often called upon to explain many of the unique characteristics of back-arc systems.

Some models of subduction systems suggest that wedge flow is governed by viscous coupling to the downgoing slab, producing flow directions parallel to the motion of the downgoing plate (McKenzie, 1979; Ribe, 1989). On the other hand, shear-wave splitting studies commonly detect fast shear-wave polarization directions that are roughly parallel to the arc (e.g., Bowman and Ando, 1987; Long and van der Hilst, 2006; Pozgay et al., 2007; Smith et al., 2001; Yang et al., 1995) and hence perpendicular to plate motion direction. For example, in the Mariana and Tonga subduction zones, fast splitting directions are parallel to the arc near the volcanic arc itself and rotate to the direction of plate convergence in the back arc (Pozgay et al., 2007; Smith et al., 2001). Since the fast direction is often taken to be the flow direction, such observations suggest that the flow pattern is dominated by arc-parallel flow above the slab as a consequence of either slab rollback (Buttles and Olson, 1998), shearing or extension in the arc-parallel direction (Hall et al., 2000), changes in slab dip (Buttles and Olson, 1998; Hall et al., 2000), or changes in convergence angle (Blackman and Kendall, 2002; Honda and Yoshida, 2005). Alternatively, it has been argued that elastic anisotropy might develop in a manner distinct from that in more typical settings; under a restricted range of conditions such as high water content and high stress, the olivine *a*-axis direction may instead align perpendicular to the direction of maximum strain, resulting in shear-wave splitting fast orientations perpendicular to mantle flow (Jung and Karato, 2001; Karato, 2003).

Another significant issue is the shape of the melting region beneath back-arc spreading centers and its relationship to wedge flow, volatiles, and subarc melting. A broadband seismic reflection study of the mantle wedge above the Tonga slab found broad regions of significant reflectivity across the wedge, which the authors ascribe to phase transitions and compositional zonation associated with extensive metasomatism via slab-derived fluids rising through the mantle wedge (Zheng et al., 2007). Mantle tomographic studies have found broad low-velocity and high-attenuation regions extending from the volcanic arc to, or beyond, the active Lau and Mariana spreading centers (Conder and Wiens, 2006; Pyle et al., 2010; Wiens et al., 2008; Zhao et al., 1997), suggestive of the broad anomalies beneath the southern EPR. However, along the Lau spreading center, petrologic and geochemical studies (Bézos et al., 2009; Escrig et al., 2009; Langmuir et al., 2006), as well as seismic and other geophysical studies of the crust formed at the spreading center (Arai and Dunn, 2014; Dunn and

Martinez, 2011; Jacobs et al., 2007), show rapid changes in crustal type and thickness as the ridge moved away from the arc. Together, these results indicate rapid transitions in mantle chemistry or mantle flow in the wedge (Dunn and Martinez, 2011) on a scale not yet resolvable by current broadband arrays. These studies indicate that as the basin opens and the spreading center migrates away from the arc, there is a rapid transition at the spreading center from accreting more arc-like magmas to more oceanic basalt-like magmas. Recently, a dense ocean-bottom and land-based broadband seismic experiment was carried out along the Eastern Lau Spreading Center to provide improved images of the mantle wedge and test models of wedge flow and melting (Songqiao et al., 2012). Results are forthcoming.

1.13.3 Formation of Oceanic Crust

Our understanding of the structure of oceanic crust produced along mid-ocean ridges has evolved considerably over the past two decades, from an early view as a layer-cake structure composed of a few seismic layers matching geologic units to a much richer and more laterally variable structure. Having now examined the seismic structure of the crust in a variety of settings, it is now understood that basic crustal structure varies with spreading rate, geodynamic setting, and time. Around the global ridge system, heat flux varies with spreading rate, and heat supply largely governs the magmatic, tectonic, and hydrothermal processes that control the formation of oceanic crust.

1.13.3.1 General Seismic Structure of the Oceanic Crust

Starting from the top, low velocities (<5 km s^{-1} P-wave velocity) and high seismic attenuation characterize the upper few hundred meters of oceanic crust; the lower boundary of which is marked by a strong velocity gradient that can be imaged with seismic reflection techniques (e.g., Christeson et al., 1996, 1994a, 1994b; Detrick et al., 1998; Harding et al., 1993; Vera and Diebold, 1994; Wilcock et al., 1995). An early interpretation of this seismic region ('layer 2A') in terms of a lithology composed of high-porosity extrusive basalts was based on analogy with ophiolite units, the seismic velocity of laboratory samples of dredged and drilled rocks, and *in situ* measurements in drill holes (see Solomon and Toomey (1992) for a review of early work). By further analogy to ophiolites, seismic layer 2A is underlain by a higher-velocity region of sheeted dikes (seismic layer 2B), followed by yet a higher-velocity region of gabbros (layer 3) (**Figure 12**); the 2/3 boundary is typically defined by a sharp, order-of-magnitude, reduction in the velocity gradient at roughly 6.5 km s^{-1}.

Recent work has both modified and disputed this simple layer-cake model. At the axis of fast- and intermediate-spreading ridges, seismic layer 2A is consistently thin but thickens rapidly within 1–2 km of the ridge axis (**Figure 13**), presumably due to a rapid buildup of the extrusive basalts on the flanks of the ridge (e.g., Harding et al., 1993; Hooft et al., 1996; Kent et al., 1994; Stakes et al., 2005). No such relationship has been clearly documented along slow-spreading ridges. Further away from the ridge, it is globally observed that layer

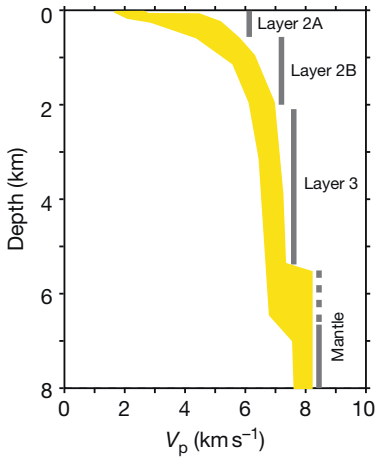

Figure 12 P-wave speed of oceanic crust. Yellow field gives approximate range of V_p values determined by several seismic experiments, mainly located on crust formed at faster spreading rates (Canales et al., 1998; Detrick et al., 1993; Dunn et al., 2000; Grevemeyer et al., 1999; Harding et al., 1993; Hussenoeder et al., 1996; Kappus et al., 1995; Tolstoy et al., 1997; Vera et al., 1990). The distinction between seismic 'layers' 2A and 2B is often made via a prominent reflector horizon observed in multichannel seismic reflection studies.

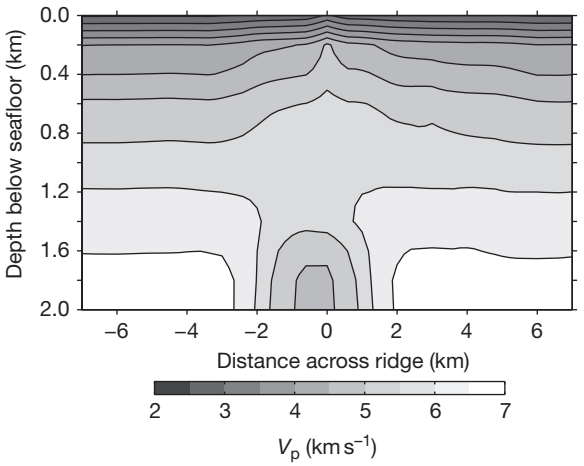

Figure 13 V_p tomographic image of the uppermost crust across the East Pacific Rise near 9°30′N latitude (an along-axis average of a 3D solution). Seismic layer 2A thickens rapidly within 2–3 km of the ridge axis ($x = 0$ km). The low-velocity body beneath the ridge axis at depths >1.2 km is the axial magmatic system. Note that the vertical exaggeration is ~4. From the seismic study of Dunn et al. (2000).

2A velocities increase with crustal age (**Figure 14**), an observation that is consistent with hydrothermal deposition in rock pores (e.g., Grevemeyer and Weigel, 1996; Grevemeyer et al., 1999; Houtz and Ewing, 1976; Purdy, 1987; Wilkens et al., 1991). The precise nature of the 2A/2B and 2/3 boundaries is still debated, and some have questioned whether they can be used to map lithologic boundaries (e.g., Christeson et al., 2007). An examination of upper crustal structure at drill hole 504B near the Costa Rica Rift (Swift et al., 1998a,b) found that the 2/3 boundary coincides with a significant decrease in bulk porosity and marks the base of the lithologic transition from extrusive rocks and intermingled dikes to

Figure 14 Average layer 2A P-wave velocity plotted by crustal age (reproduced from Grevemeyer I, Kaul N, Villinger H, and Weigel W (1999) Hydrothermal activity and the evolution of the seismic properties of upper oceanic crust. *Journal of Geophysical Research* 104(B3): 5069–5079; Nedimović et al., 2008). While the global trend (solid black circles; Carlson (1998)) exhibits a consistent increase in velocity with crustal age, there are differences in both the absolute velocity and the rate of change for different spreading centers. Colored symbols are from different portions of the Juan de Fuca spreading system; black stars and other symbols are from various East Pacific Rise and Mid-Atlantic Ridge studies.

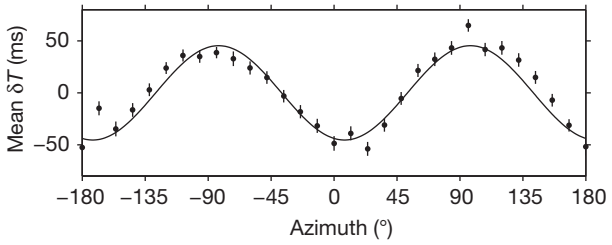

Figure 15 Variation of P-wave travel times with ray path azimuth from the L-SCAN seismic study of the crust along the Eastern Lau Spreading Center (Dunn and Martinez, 2011). Zero azimuth is parallel to the spreading axis. Travel times are calculated with respect to a one-dimensional (depth-varying) velocity model and binned by azimuth; error bars give the $1-\sigma$ spread of the values for that bin. P-waves travel faster (negative values) parallel to the spreading axis and slower (positive values) perpendicular to the axis.

mainly dikes. Thus, seismic layer 3 is expected to contain dikes underlain by gabbros. On the other hand, a study at drill hole 1256D (Wilson et al., 2006) found some gabbro at depths shallower than the seismic 2/3 boundary, but the top of the main gabbroic section is located at the depth predicted by seismic measurements. Along slow-spreading ridges, significant tectonic modification of the crust is expected (e.g., Cannat, 1993, 1996) and the layer-cake model probably does not apply over large sections of crust produced at such ridges. Since many studies show that seismic wave speed is very sensitive to porosity and not necessarily general lithology, most seismologists remain cautious about directly correlating seismic structure with lithologic units.

At the seafloor, high-resolution acoustic imaging reveals that faults, fissures, and fractures pervade the shallow oceanic crust. The orientation of these features is sensitive to the local stress field, and they tend to align perpendicular to the minimum compressive stress, which is generally parallel to mid-ocean ridges. At depth, aligned cracks are detectable by their seismic anisotropy signature, via either shear-wave splitting and polarization measurements (e.g., Barclay and Toomey, 2003; Stephen, 1981) or azimuthal variations in travel times (e.g., Barclay et al., 1998; Dunn and Toomey, 2001; Dunn et al., 2005; Little and Stephen, 1985; Menke et al., 1994; Shearer and Orcutt, 1985; Sohn et al., 1997; White and Whitmarsh, 1984). Along ridges, P-wave travel times exhibit a cosine(2θ) variation, where θ is the ray azimuth (**Figure 15**). A 2θ pattern indicates that the travel-time signal is dominated by water-saturated vertically aligned cracks with aspect ratios >0.01 (Hudson, 1981). Two studies (Tong et al., 2004, 2005) have examined both 2θ and 4θ patterns in travel-time residuals (crack aspect ratios <0.01 give rise to a dominant cosine(4θ) signal (Hudson, 1981)) and used the ratio of the amplitudes of these signals to examine local variations in subsurface crack structures. The best-resolved seismic studies detect around 3–4% anisotropy in the upper 2–4 km of the crust, essentially within seismic layer 2 (e.g., Barclay et al., 1998; Dunn and Toomey, 2001; Dunn et al., 2005, 2013; Seher et al., 2010a,b; Sohn et al., 1997; Tong et al., 2004). Using Hudson's crack theory (1981) and 4% anisotropy, aligned cracks with aspect ratios of 0.01–0.1 give rise to porosities of $\leq$1%, a value much less than the total expected porosity based on the reduction of the isotropic velocities alone (>10%). However, because the permeability of rock with aligned cracks can be several orders of magnitude larger than rock without aligned cracks (De Weist, 1965; Fisher, 1998), such cracks may provide the dominant pathways for hydrothermal circulation to cool and chemically alter the crust.

The middle to lower crust is characterized by low-velocity gradients, a general absence of seismic reflectors, and seismic velocities in the 6–7 km s^{-1} range (e.g., Canales et al., 1998, 2003; Dunn and Martinez, 2011; Dunn et al., 2005; Spudich and Orcutt, 1980; van Avendonk et al., 2001; Vera et al., 1990). Because of the gentle velocity gradients, less seismic energy turns at these depths, making this a more difficult region to study in detail. Seismic reflections from the Moho can be used to study this region, but for seismic experiments with low data coverage, or mainly vertically incident energy, there can be a large trade-off between lower crustal velocities and Moho depth (e.g., Ross, 1994). Therefore, a dense station spacing (station spacing < crustal thickness) and a large range of source-to-station offsets are required to accurately determine the structure over this depth interval.

Few seismic studies have attempted to constrain the detailed nature of the crust–mantle transition or the 'Moho.' Along intermediate- and fast-spreading ridges, the Moho produces vertically incident (e.g., Detrick et al., 1987) and strong wide-angle seismic reflections (e.g., Canales et al., 2003; Vera et al., 1990) and appears to be a relatively sharp transition region (<1 km thick) from crustal to mantle velocities (**Figure 16**). Along slow-spreading ridges, the Moho is less well defined and often absent in vertical-incident data; wide-angle data reveal both regions of sharp transition and regions of gradual transition (Canales et al., 2000a,b; Dunn et al., 2005; Hooft et al., 2000; Hosford et al., 2001). A thick transition suggests that crustal construction is complex, perhaps due

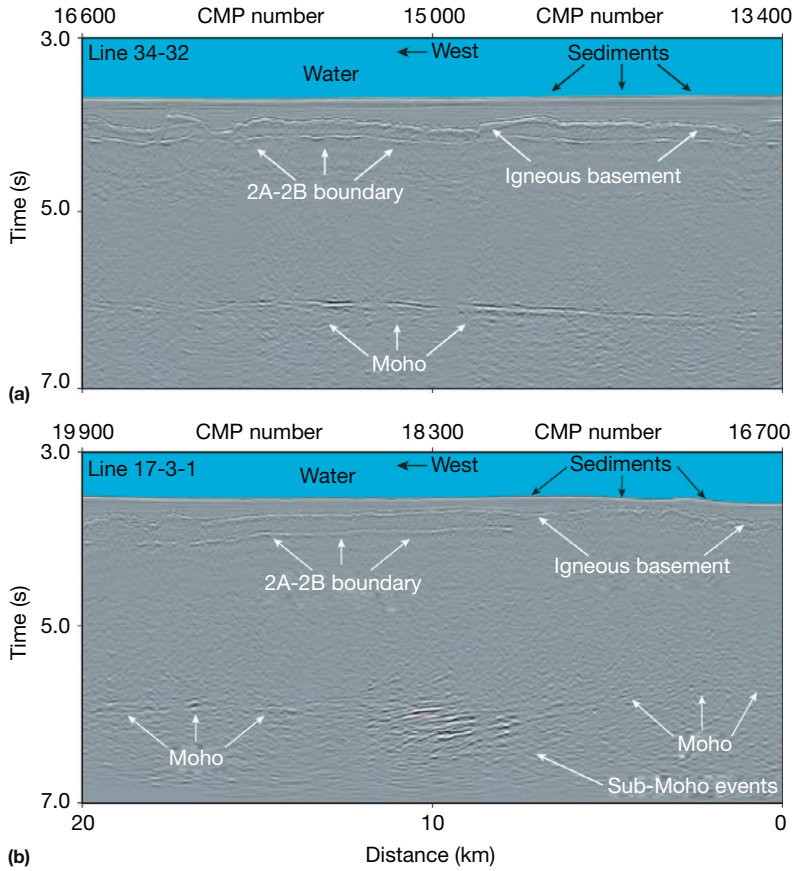

Figure 16 Seismic reflection structure of oceanic crust from two ridge flank regions of the Juan de Fuca Ridge (intermediate-rate spreading). Plots show variability of the Moho structure from area to area. (a) A sharp/bright Moho reflection and (b) a variable strength Moho reflection: regions of weaker and variable strength Moho reflection flank a region with clusters of sub-Moho reflectors interpreted as gabbroic sills. to melt accumulation and layering over a large depth interval. Alternatively, and especially near fracture zones, a thick transition may indicate serpentinization of the upper several hundred meters of mantle. Beneath the Moho, mantle velocities are largely anisotropic (e.g., Dunn et al., 2005; Raitt et al., 1969; Toomey et al., 2007) with a cosine(2θ) azimuthal variation in P-wave velocities (where θ is the ray path azimuth) (Figure 17). This anisotropy is largely attributed to the alignment of the *a*-axes of mantle olivine in the spreading direction.

Oceanic crustal thickness is a key measure of the ongoing chemical differentiation of the planet and was once thought of as being relatively uniform throughout the oceans, with an average thickness of about 6–7 km (Figure 10). Our current understanding is that only fast-spreading ridges produce a relatively uniform thickness crust, and even in those environments, local variations may exceed 1 km (e.g., Canales et al., 1998). Slow-spreading ridges, on the other hand, produce a wide range of crustal thicknesses but may still exhibit an average seismic thickness of ~6 km when averaged over tens of kilometers. Occasionally, little to no crust is produced, as documented by mantle rocks found at the seafloor (e.g., Cannat, 1993, 1996), such as near cold fracture zones or as magmatism waxes and wanes at the spreading center. At full spreading rates <2 cm year^{-1} ('ultraslow spreading'), crustal thickness drops off sharply (Figure 10). In general however, too few modern seismic studies have documented crustal thickness along spreading centers, and thus, any relationship between crustal thickness and spreading rate is still approximate at best. Furthermore, because serpentinized mantle exhibits crustal velocities, crustal thickness estimates derived from seismic experiments in intermediate- to slow-spreading environments (or any areas where intense faulting may permit deep penetration of seawater) remain controversial.

1.13.3.2 Fast-Spreading Ridges

The fastest spreading rates, >90 mm year^{-1}, are principally found along the EPR. Seismic studies along the EPR have determined details of the structure of the crust and the overall ridge magmatic system from the seafloor well into the mantle, including the width, magnitude, and ridge-parallel variations of this system at most depths. Crustal seismic structure along fast-spreading ridges tends to be more laterally uniform than that produced along slower-spreading ridges, suggesting a fairly uniform supply of melt from the mantle. Here, the layer-cake model of seismic structure is most applicable.

Beneath the EPR, the mantle upwelling zone is expected to be >300 km wide (Forsyth et al., 1998). However, just below the base of the crust, the bulk of the low-velocity zone narrows to perhaps ~40 km wide (Figure 18), and in the lower crust,

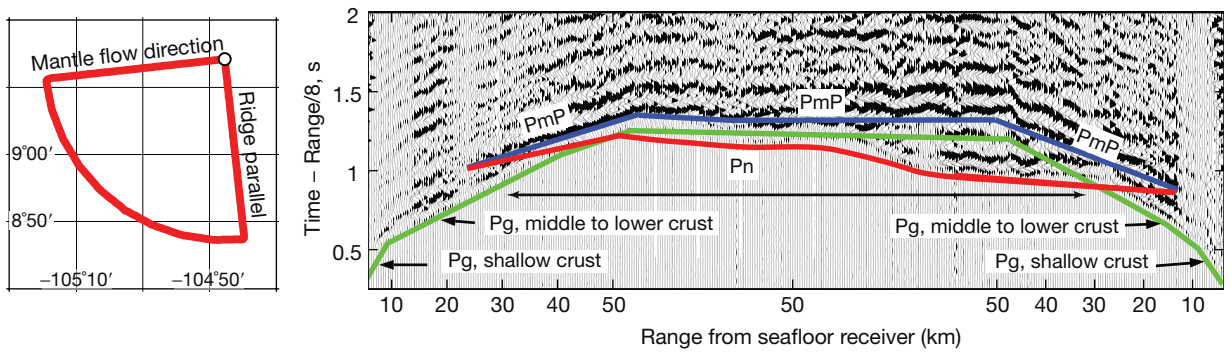

Figure 17 Azimuthal P-wave anisotropy in the mantle on the western flank of the East Pacific Rise. (Left) Location of an ocean-bottom seismograph (white circle) and air gun shot pattern (red lines). (Right) Seismic record section showing crustal-refracted (Pg), Moho-reflected (PmP), and mantle-refracted (Pn) energy recorded by the station. Shots along a line that parallels the mantle flow direction exhibit earlier arriving Pn energy (<1 s at ~32 km offset; right side of record section), and shots along a line that parallels the ridge axis exhibit later arriving Pn energy (>1 s at 50 km offset; left side of record section), yet crustal thickness (as indicated by the PmP arrivals) and crustal velocities (as indicated by Pg arrivals) change insignificantly around the semicircle. Refraction studies shot in the slow anisotropy direction may find only a small difference between lower crustal and mantle velocities. Data from the UNDERSHOOT experiment (Toomey et al., 2007).

the seismic low-velocity region abruptly decreases to only 7–8 km wide. Active-source tomographic (Dunn et al., 2000) and seafloor compliance studies (Crawford and Webb, 2002) of the crustal magmatic system detect a narrow low-velocity zone from the base of the crust up to within ~1.5 km of the seafloor (**Figure 19**). At its top, the low-velocity zone may be about 50% as wide as near the base.

Since the inferred isotherms for this narrow seismic structure do not conform to the predictions of a conductively cooled magmatic system (**Figure 20**), the implication is that hydrothermal circulation penetrates deeply off-axis to cool the lower crust (Cherkaoui et al., 2003; Dunn et al., 2000). Lower crustal hydrothermal circulation has also been suggested from studies of the Oman ophiolite, which indicate that zones of narrow hydrothermal circulation extracted heat from either side of a crustal magmatic system to depths of 5–6 km (Coogan et al., 2006; Gregory and Taylor, 1981; Nehlig and Juteau, 1982). However, other studies of ophiolite chemistry suggest that more pervasive hydrothermal circulation decays exponentially with depth (Coogan et al., 2002). The idea that hydrothermal fluids might penetrate to the Moho on the flanks of the ridge is highly contentious, and part of the problem is that direct observations of hydrothermal circulation are limited to the regions of highest heat output at the ridge axis, as opposed to regions of lower-level flow (inflow or outflow) off-axis.

The low velocities (Dunn et al., 2000) and high-attenuation values (Wilcock et al., 1992, 1995) of the magmatic system are consistent with 10–40% melt in the middle to upper crust, 2–8% melt in the lower crust, and 3–12% melt near the Moho transition zone (**Figure 20**). The large uncertainty of these estimates is partly due to a lack of laboratory studies on partially molten crustal rocks to determine their physical properties under *in situ* conditions at seismic frequencies. Within the middle to lower crust, the absolute magnitudes of the velocity and attenuation anomalies decrease with increasing depth (Dunn et al., 2000; Toomey et al., 1990; Vera et al., 1990; Wilcock et al., 1995) such that the lower crust is estimated to contain the least melt, both by melt fraction and by total volume, which may indicate that it is closer to its solidus than the other regions (Sinton and Detrick, 1992). A few seismic and compliance studies indicate that magma sills accumulate near the crust–mantle transition zone or Moho (Crawford and Webb, 2002; Crawford et al., 1999; Garmany, 1989; Nedimović et al., 2005), possibly within a broader region of low melt fraction (Dunn and Toomey, 1997). Observations of a substantial amount of melt at this depth indicate an impediment to upward flow. The density contrast at the Moho (Crawford et al., 1999), a permeability barrier due to crystallization at the base of the crust (Kelemen et al., 1997; Korenaga and Kelemen, 1997), and changes in the stress conditions (Ildefonse et al., 1993) have been suggested as possible barriers to melt migration.

Multichannel seismic (MCS) reflection imaging shows that melt accumulates at the top of the magmatic system, beneath either a permeability or viscosity barrier, within a small melt lens (e.g., Detrick et al., 1987; Kent et al., 1993; Mutter et al., 1988). The lens is often narrow and thin (about 1 km wide and 10–50 m thick; e.g., Kent et al., 1993) with high melt content, but its size varies by location and it can range from mostly crystalline to mostly molten (e.g., Babcock et al., 1998; Collier and Singh, 1997; Harding et al., 1989; Kent et al., 1993, 2000; Singh et al., 1998). Just above the melt lens, waveform analysis of MCS reflection data reveals a thin high-velocity 'lid' (Singh et al., 1999; Vera et al., 1990), which is interpreted as a solid region, devoid of melt or hydrothermal cracks, that acts as a conductive cooling regime between the hydrothermal system above and the melt lens below. Along-axis variations in the thermal structure above the melt lens appear to correlate with small ridge discontinuities (Tian et al., 2000; Toomey et al., 1994). The depth of the lens is expected to be controlled by the trade-off between the rate of heat input from below and the rate of heat extraction via hydrothermal circulation from above (e.g., Hooft and Detrick, 1993). Thus, the melt lens tends to deepen as the spreading rate, and heat/melt supply from below drops (**Figure 9**; Purdy et al., 1992). Although the highest concentrations of melt are thought to occur within the melt lens, a rough estimate of the total distribution of melt in the

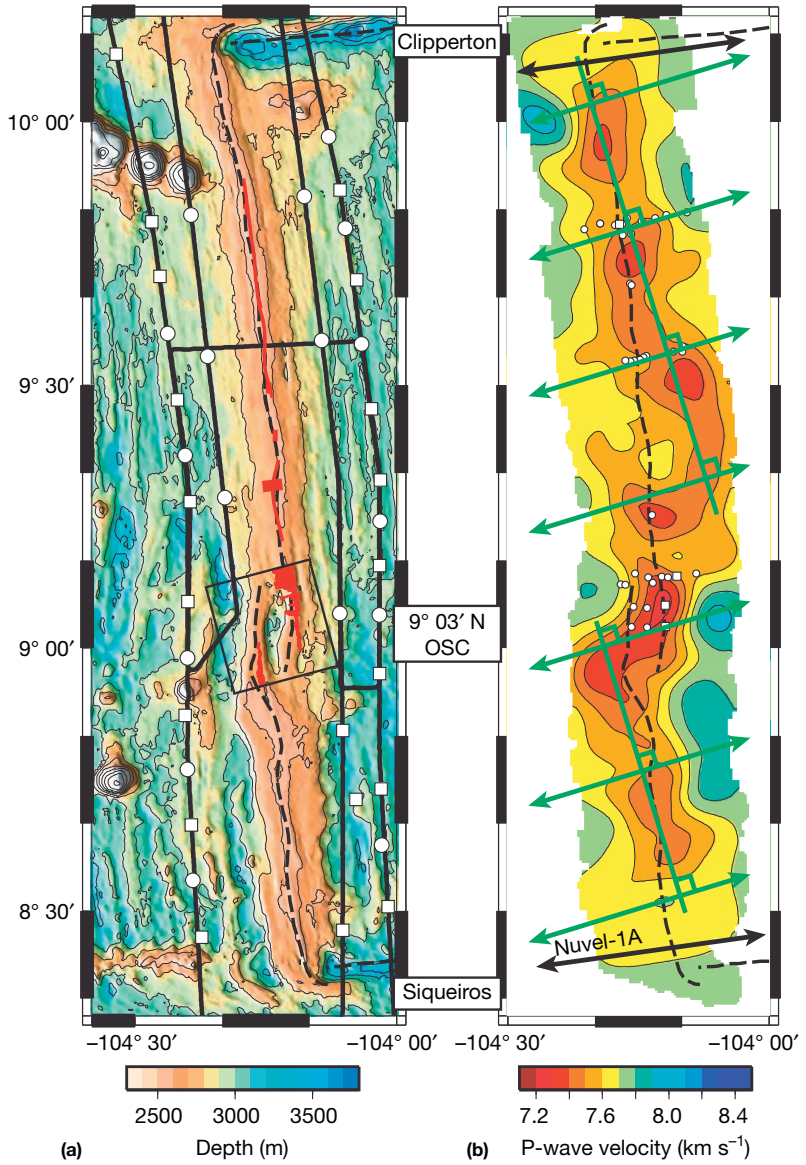

Figure 18 (a) Bathymetric map of the East Pacific Rise, 9° N region, along with the location of seismic instruments (white circles and squares) and air gun shots (black lines). Red areas indicate location of a melt lens reflector, where known. (b) P-wave tomographic image of the upper mantle just beneath the crust; contour interval is 0.1 km s^{-1}. Black arrows indicate plate spreading direction. Green arrows indicate the inferred mantle flow direction. Black dashed curve indicates the location of the ridge axis. Reproduced from Toomey DR, Jousselin D, Dunn RA, Wilcock WSD, and Detrick RS (2007) Skew of mantle upwelling beneath the East Pacific Rise governs segmentation. *Nature* 446: 409–414. http://dx.doi.org/10.1038/nature05679.

crust suggests that, by volume, there is more melt in the middle to lower crust and Moho regions than in the shallow melt lens, simply because of the greater cross-sectional areas of these regions (Dunn et al., 2000); deep melt lenses near the Moho may also contain large amounts of melt (Crawford and Webb, 2002; Crawford et al., 1999; Garmany, 1989).

Microearthquake studies using closely spaced networks of seafloor seismographs detect tens of thousands of events along ridge segments over spans of several months. A large proportion of these events occur above the shallow melt lens at the ridge crest and may be related to hydrothermal cracking, faulting, and, more rarely, dike injection (Sohn et al., 2004; Tolstoy et al., 2008; Wilcock et al., 2009). In one study (Tolstoy et al., 2008), hypocenters beneath a hydrothermal vent field on the EPR cluster in a vertical pipelike zone that lies above the shallow axial melt lens, suggesting that the events are mainly hydrothermal in nature and mark the location of very active fluid flow. A few studies indicate that tidally induced stresses within the upper crust modulate microearthquake origin times (Stroup et al., 2007, 2009; Tolstoy et al., 2002; Wilcock, 2001). At the northern EPR, a relationship between peak microearthquake activity and maximum predicted tidal extension has been interpreted to result from pore-pressure perturbations propagating laterally through the hydrothermal system (Stroup et al., 2009).

While the upper crust is widely believed to be emplaced via repeated dike injections from the top of the shallow melt lens, thus forming sheeted dikes and extrusive rock units, there is no

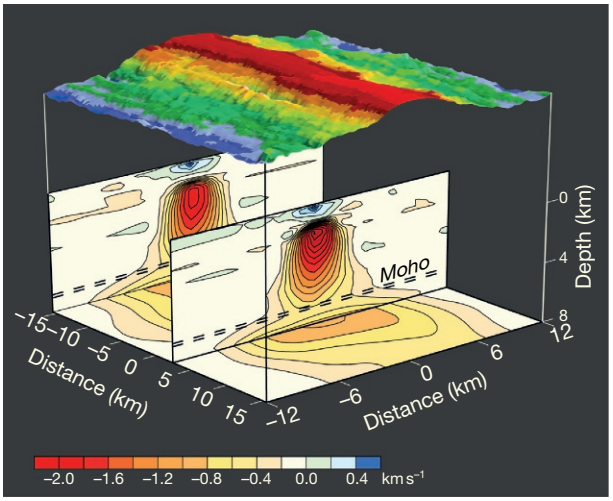

Figure 19 Three-dimensional tomographic image of the crustal magmatic system beneath the East Pacific Rise, 9°30′N. Contours of 0.2 km s^{-1} are relative to a background one-dimensional depth-varying velocity model. Low velocities are indicative of high temperatures and melt within a narrow magmatic system. A small and thin subaxial melt lens, observed in multichannel reflection data, passes along the low-velocity region at 1.5 km depth (not shown). Solution from Dunn et al. (2000).

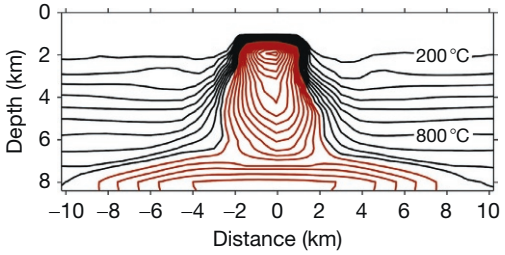

Figure 20 Estimated temperatures (black contours, 100° intervals) and melt content (red contours) beneath the East Pacific Rise. Estimated melt fraction depends on the dominant shape of the melt pockets. Assuming melt resides in thin films (aspect ratio = 0.05) gives a contour interval of 0.8% and a peak melt content of ~10%. Assuming that melt resides in equant-shaped pockets gives a contour interval of 2% and a peak melt content of 28%. Calculations are made assuming that seismic anelasticity is important. Estimates are based on the results of Dunn et al. (2000).

general agreement on the formation of the lower crust. For over two decades, there have been many attempts to reconcile the geophysical observations from the EPR and petrologic and structural observations in the Oman ophiolite. This work has led to a variety of models for the formation of the lower crust that are defined by two end-members. In the gabbro glacier or conveyor belt models (e.g., Henstock et al., 1993; Nicolas et al., 1988, 1993; Phipps Morgan and Chen, 1993a; Quick and Denlinger, 1993), the gabbros crystallize in a small magma lens at the dike/gabbro boundary and then subside to form the lower crust. In the sheeted sill model (e.g., Boudier et al., 1996; Kelemen and Aharonov, 1998; Kelemen et al., 1997; MacLeod and Yaouancq, 2000), magma moves upward through a series of thin sills and the lower crust crystallizes *in situ*. Hybrid models combine varying proportions of gabbro flow and sill emplacement and/or include crystallization in a pair of magma lenses, one located at the dike/gabbro boundary and the other at the base of the crust (Boudier et al., 1996; Chen, 2001; Chenevez et al., 1998; Maclennan et al., 2004). Several arguments have been made both for and against each of the models mentioned earlier (see Cherkaoui et al. (2003) for a brief review of older work), and to date, there is no clear seismic evidence for stacks of melt lenses in the lower crust (e.g., Singh et al., 2006a,b).

There is growing evidence that not all mantle melts are directly focused upward to the narrow crustal magmatic system. Garmany (1989), using P-to-S converted seismic phases, first suggested the presence of deep melt lenses forming at the crust–mantle boundary away from the axis of a fast-spreading ridge. More recently, Durant and Toomey (2009), using wide-angle refraction data, found evidence for the presence of high temperatures and perhaps melt in an isolated area roughly 20 km from the axis of the EPR – well outside of the low-velocity region that characterizes the subridge crustal magmatic system. Using MCS data, Canales et al. (2012) show evidence for a network of melt lenses located 4–8 km from the axis of the EPR, outside of the main axial zone of crustal accretion but above a region that is expected to be partially molten. Pockets of melt observed to extend from the off-axis sills inward to the axial zone might represent melt migration pathways. To date, it appears that off-axis melt supply to the crust may only make up a tiny fraction of the overall crustal production that occurs along fast-spreading ridges. Nevertheless, more observations such as these will probably be forthcoming, and they will provide important insight into processes of melt supply to ridges.

Along the EPR, the ridge axis is segmented on a variety of scales, and the deepest portions of the ridge are often located near large tectonic offsets, such as at the tips of propagating ridges and at transform faults (e.g., Macdonald, 1998). Transform faults are long-lasting features that can offset ridges by one hundred or more kilometers, though usually less, and leave large fracture zones in their wakes. Only a few seismic studies have examined their structure (e.g., McGuire et al., 2012; Roland et al., 2012; van Avendonk et al., 1998, 2001), and these studies are mainly limited to imaging at crustal depths. A recent detailed study by Roland et al., 2012 shows that transform fault traces are associated with broad seismic low-velocity zones (**Figure 21**) and intense seismicity. The zones are >5 km wide in the shallow crust and as wide as 2 km at the base of the crust, and they are interpreted to be wide, compliant zones of enhanced fracturing and porosity.

Between transform offsets, fast-spreading ridges are segmented by both small bends in the ridge axis and larger overlapping offsets. The origin of this segmentation is controversial. By one view, they result directly from 3D mantle upwelling. Alternatively, some types of segmentation may be regulated by the tectonic rifting of young lithosphere and thus only indirectly linked to the form of mantle upwelling. Central to the controversy is the origin of OSCs. OSCs are segment boundaries characterized by the overlap of two en echelon ridge segments that offset the axial neovolcanic zone by a few hundred meters to many kilometers. Unlike transform offsets, OSCs can migrate along the ridge, as the individual ridge limbs

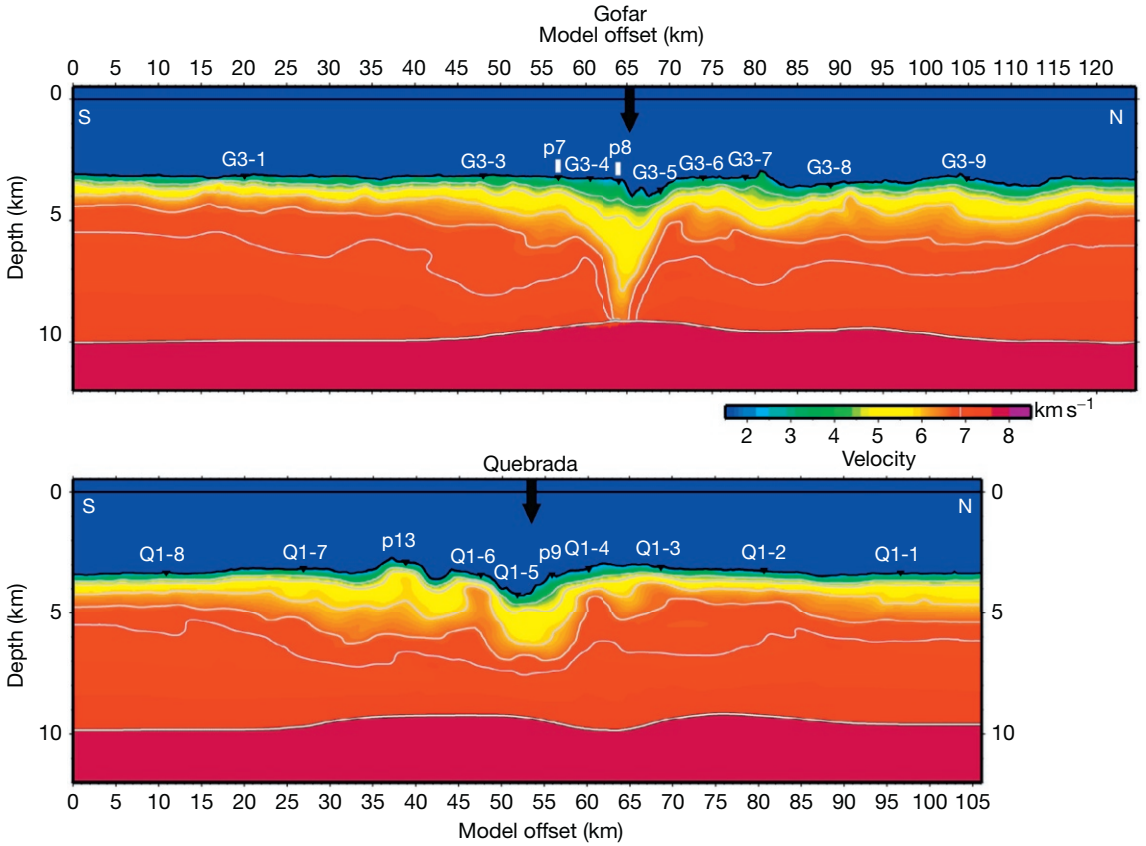

Figure 21 P-wave velocity profiles across the Gofar (top) and Quebrada (bottom) fault system on the southern East Pacific Rise determined from wide-angle refraction data sets. Deepest white line shows the location of the Moho reflector. Velocity is contoured at 4.2, 5.0, 6.0, 6.6, and 7.0 km s^{-1}. Black arrows show the approximate location of the active transform fault. Reproduced from Roland E, Lizarralde D, McGuire JJ, and Collins JA (2012) Seismic velocity constraints on the material properties that control earthquake behavior at the Quebrada-Discovery-Gofar transform faults, East Pacific Rise. *Journal of Geophysical Research* 117: B11102. http://dx.doi.org/10.1029/2012JB009422.

propagate or recede (Carbotte and Macdonald, 1992, 1994; Macdonald et al., 1988). The structural evolution of OSCs has led some to speculate that their origin is the result of fluctuations in axial magmatic processes (e.g., Macdonald et al., 1984, 1988, 1991) and that OSCs occur above regions of reduced magma supply, perhaps at the boundary between two widely separated regions of mantle upwelling (Schouten et al., 1985). An opposing model states that OSCs are the result of tectonic processes, a response to changes in regional strain, such as those arising from changes in the kinematics of spreading (Lonsdale, 1983, 1986, 1989; Macdonald et al., 1984). In this hypothesis, the magma supply beneath the OSC is uninterrupted. The observation that most OSCs on the Pacific–Cocos plate boundary share a right lateral offset suggests that the offsets formed in response to a recent counterclockwise rotation in the direction of spreading (Carbotte and Macdonald, 1992, 1994), such that the new forces on the plate boundary lead to the segmentation of the ridge and the formation of OSCs. Three-dimensional MCS and refraction surveys of an OSC at 9°03′N on the EPR indicate that melts that feed the limbs of the OSC rise up directly from the mantle beneath the OSC itself (Bazin et al., 2003; Kent et al., 2000). Furthermore, an active-source tomographic study of the mantle beneath the 9°03′N OSC (Toomey et al., 2007) did not find a reduction in the size or magnitude of the mantle low-velocity zone beneath the OSC as compared to other areas beneath the EPR (**Figure 18**). Studies of crustal thickness produced in the wakes of OSCs have not consistently found thinner crust in those areas (Barth and Mutter, 1996; Bazin et al., 1998). Together, these results indicate that melt supply is fairly uniform along the ridge beneath OSCs over long timescales.

On a smaller scale, segments of the EPR bounded by minor morphological deviations from axial linearity or 'devals' (Langmuir et al, 1986) of 5–25 km length may be associated with separate shallow volcanic systems (Haymon et al., 1991) and higher proportions of melt at depth (Dunn and Toomey, 1997; Dunn et al., 2000; Toomey et al., 1990, 1994). Seismic tomographic studies of the EPR (Dunn and Toomey, 1997; Dunn et al., 2000; Toomey et al., 1990; 2007) reveal that both the crustal low-velocity region and the mantle low-velocity region vary along the rise on a scale comparable to the deval segmentation, with lower velocities generally located at the centers of each segment (**Figure 18**). In some instances, the seismic reflector that defines the crustal melt lens also changes in character near devals (e.g., Kent et al., 1993). These studies suggest that crustal magma chambers are replenished from the mantle at closely spaced intervals. To produce these small variations, the mantle melt supply may be locally

enhanced by mantle temperature variations (Thompson, 1987); compositional heterogeneity (Langmuir et al., 1986; Pickering-Witter and Johnston, 2000); 3D melt segregation and transport mechanisms, such as the coalescence of small-scale melt segregations, veins, dikes, or dissolution channels (e.g., Kelemen et al., 1995; Nicolas, 1989; Sleep, 1988; Stevenson, 1989); or diapirism (Boudier et al., 1997; Ceuleneer and Nicolas, 1985; Jousselin et al., 1998; Nicolas and Boudier, 1995; Nicolas and Violette, 1982; Nicolas et al., 1994; Whitehead et al., 1984). Evidence for mantle diapirs has been found in the Oman ophiolite, the largest of which have a characteristic radius that is generally small – about 3 km (defined by the region of inferred vertical flow). Such features have been mapped at intervals of a few tens of kilometers along the paleoridge axis; some are spaced as close as 10 km (Boudier et al., 1997). However, the scale of the diapiric flow is expected to be smaller than current seismic experiments are capable of resolving (Jousselin et al., 2003), and no direct evidence for diapiric mantle flow beneath an active ridge has been detected.

1.13.3.3 Intermediate-Spreading Ridges

Mid-ocean ridges with intermediate spreading rates of roughly 55–85 mm year^{-1} include the Juan de Fuca Ridge (JdFR), Southeast Indian Ridge (SEIR), Pacific–Antarctic Ridge, Galápagos Spreading Center (GSC), and Chile Rise (**Figure 1**). Some back-arc systems also open at intermediate rates. Crust produced along the ridges tends to be 5–7 km thick (**Figure 10**), in the same range as for faster-spreading ridges. In addition, seismic layer 2A (**Figure 22**) is observed to thicken rapidly within 1–2 km of the ridge axis (e.g., Baran et al., 2010; Canales et al., 2005). Together, these observations suggest a similar crustal emplacement history for both intermediate- and fast-spreading ridges. However, instead of a shallow topographic rise at the ridge axis, intermediate-rate ridges have more variable topography, ranging from rifted axial deeps to rises. In many places, the axis of the ridge deepens substantially toward a major ridge offset. Upper crustal P-wave velocities also appear to be slower on average than that produced at faster spreading rates (e.g., see compilation in Figure 6 of Jacobs et al. (2007)). These and other observations have led many to suggest that lower heat influx to these ridges, due to their slower spreading rates, results in episodic crustal melt storage, a thicker effective lithosphere, and a greater degree of cracking and faulting of the ridge axis.

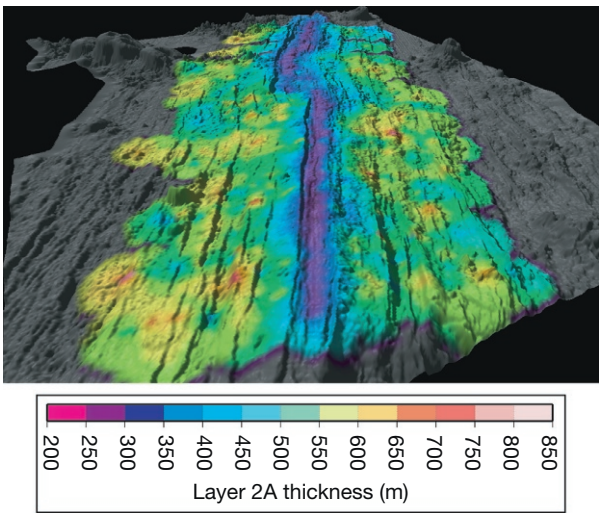

Figure 22 Three-dimensional perspective view of the layer 2A thickness draped over seafloor topography. Layer 2A thickness is often considered to be a proxy for the thickness of the volcanic, extrusive layer of the upper crust. Reproduced from Canales JP, Detrick RS, Carbotte SM, et al. (2005) Upper crustal structure and axial topography at intermediate-spreading ridges: Seismic constraints from the Southern Juan de Fuca Ridge. *Journal of Geophysical Research* 110: B12104. http://dx.doi.org/10.1029/2005JB003630.

On the basis of gravity profiles derived from GEOSAT radar altimetry, Small and Sandwell (1989) suggested that a threshold-type mechanism governs ridge axis form; this and several subsequent studies found an abrupt switchover from a smooth axial high morphology to rough axial deeps at intermediate spreading rates of roughly 60–70 mm year^{-1} (e.g., Malinverno, 1993; Small, 1998; Small and Sandwell, 1992, 1994). Within that narrow range of spreading rates, the morphology of the ridges is highly variable from one to the next, and several studies have put forth the hypothesis that intermediate-spreading ridges evolve through cycles of magmatic and tectonic spreading (Kappel and Normark, 1987; Kappel and Ryan, 1986; Perfit and Chadwick, 1998; Smith et al., 1994). It has been suggested that the key influence on whether the ridge axis is in a state of magmatic versus tectonic opening is the presence or lack of a crustal magmatic system, which would influence the thermal structure and the strength of the crust (e.g., Perfit and Chadwick, 1998). A modeling study by Phipps Morgan and Chen (1993a,b) suggested that intermediate-spreading ridges are in a delicate balance either supporting a crustal magma chamber or not, and this threshold-like sensitivity leads to the observed large changes in ridge morphology.

A series of recent seismic studies along the JdFR, GSC, and SEIR have shed new light on this issue. Contrary to earlier expectations, MCS data reveal shallow axial melt lenses beneath all JdFR segments (**Figure 23**), including those previously assumed to be in a tectonic phase of extension (Canales et al., 2005, 2006; Carbotte et al, 2006, 2008; van Ark et al., 2007). Similarly, some segments of the SEIR and GSC are underlain by an axial melt lens (Baran et al., 2010; Blacic et al., 2004), even though in some cases, they may exhibit deeper and more heavily rifted axes. As compared to faster-spreading ridges, the depth of the melt lens is more variable along intermediate-spreading ridges. Individual ridge segments are associated with distinct lens depths, and along a single spreading segment, the depth of the lens is also often correlated with seafloor axial depth (**Figure 23**). Lens depth can also be correlated with the presence or absence of an axial summit graben. Thus, while the absence or presence of a melt lens, or larger crustal magmatic system, may have a large influence on axial thermal structure and strength, it appears that subtle variations of melt lens depth can also have a large control on ridge morphology (Carbotte et al., 2006).

The growth of layer 2A within a few kilometers of the ridge is often considered to be a measure of the volcanic construction of the upper crust. While the growth of layer 2A at intermediate-rate ridges can be similar to that along faster-

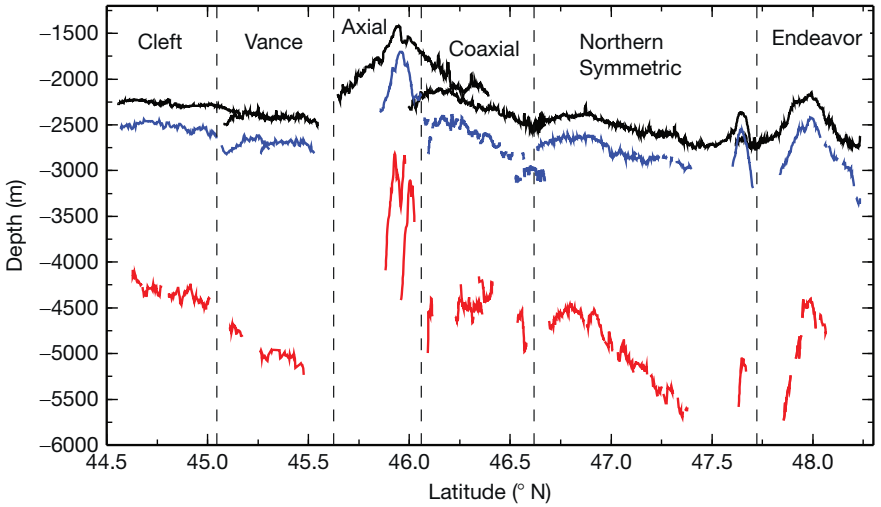

Figure 23 Estimates of the depth beneath the seafloor (black) of seismic layer 2A (blue) and melt lens (red), beneath the segments of the Juan de Fuca Ridge. Reproduced from Carbotte SM, Nedimović MR, Canales JP, Kent GM, Harding AJ, and Marjanović M (2008) Variable crustal structure along the Juan de Fuca Ridge: Influence of on-axis hot spots and absolute plate motions. *Geochemistry Geophysics Geosystems* 9: Q08001. http://dx.doi.org/10.1029/2007GC001922.

spreading ridges (e.g., Canales et al., 2005; **Figure 22**), differences in growth along the Cleft, Vance, and Endeavor segments of the JdFR suggest somewhat different modes of extrusion and upper crustal formation for each segment. Therefore, processes of lava emplacement and distribution on the seafloor may be modulated by magma supply (Canales et al., 2005).

The presence of a partially molten lens along sections of ridge without an axial rise argues against prior hypotheses that hydrothermal heat extraction along such ridges is driven by the propagation of a cracking front down into a frozen magma chamber (Wilcock and Delaney, 1996). Instead, the hydrothermal systems, like those at the EPR, appear to be driven by heat extraction from a crustal magma body (e.g., van Ark et al., 2007). Morphological and hydrothermal differences between the intermediate-spreading ridge and the fast-spreading EPR can be attributed to the greater depth of the JdFR melt lenses (2–3.3 vs. 0.5–1.5 km; Kent et al., 1993) and the correspondingly cooler, more brittle shallow crust overlying the lens (van Ark et al., 2007). Variations in the seismic properties of the melt lens, and by inference the melt/crystal ratio, correlate with lava chemistry (Smith et al., 1994) and with the location of hydrothermal plumes (Baker, 1994), suggesting that high-temperature hydrothermal venting along intermediate-spreading ridges is closely linked to the physical state of the underlying melt lens (Canales et al., 2006).

Strong P-wave reflections near the Moho transition zone have been found in JdFR MCS data, located both near the ridge axis (<20 km) and near the outer wakes of propagators on the ridge flanks (Nedimović et al., 2005). Groups of reflections found near the ridge axis could correspond to gabbroic melt lenses emplaced during magma delivery to the axis. Reflection events within the propagator wakes may be frozen melt sills injected at the base of the crust during ridge propagation. At the propagator tips, the ridge propagates into relatively cool lithosphere, which may enhance sill emplacement and rapid solidification (Nedimović et al., 2005).

1.13.3.4 Slow-Spreading Ridges

Slow-spreading ridges, with opening rates of roughly 20–50 mm year^{-1}, include the MAR, Central Indian Ridge, and several back-arc spreading centers. The seafloor morphology and seismic structure of the lithosphere along the ridges is highly variable, indicating that as spreading rate drops, processes of crustal formation become more 3D and tectonic complexity increases. Upper crustal velocities tend to be lower than for faster-spreading ridges and do not include a narrow high-velocity region along the ridge axis that is typical for faster-spreading-rate ridges (e.g., **Figures 13** and **22**), and the neovolcanic zone at the ridge axis is usually not well defined. Crustal thickness estimates via seismic studies are few and reveal that crustal thickness can vary widely from values near zero to as much as 9 km, though the average may be around 6 km (**Figure 20**).

Several observations indicate that the upper 3–4 km or more of crust is, in general, cool and brittle along slow-spreading ridges. The low-velocity layer, seismic layer 2, is usually observed throughout the top 1–2 km of the crust (Barclay et al., 1998; Canales et al., 2000a; Dunn et al., 2005; Hooft et al., 2000; Hosford et al., 2001; Hussenoeder et al., 2002) and is generally accepted to be the result of a high proportion of pores and cracks at these depths. In the upper crust, the detection of microearthquakes (e.g., Barclay et al., 2001), the ratio of P- to S-wave velocity (Barclay et al., 2001), and the presence of seismic anisotropy (Barclay and Toomey, 2003; Dunn et al., 2005; Seher et al., 2010a,b) reveal that the upper 2–4 km or more of crust is generally pervaded with faults and cracks and is thus relatively cool and brittle. The seismic structure of the upper crust is laterally variable and appears to reflect a variety of processes, such as tectonic modification, volcanic flux variations, and crustal aging (Arnulf et al., 2012; Barclay et al., 1998; Dunn et al., 2005; Hosford et al., 2001; Hussenoeder et al., 2002; Magde et al., 2000). In contrast to faster-spreading ridges

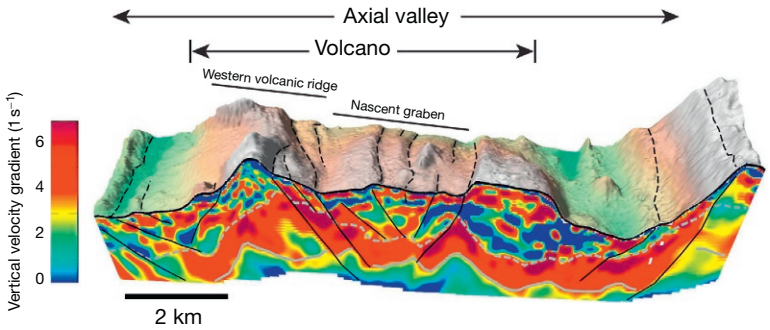

Figure 24 Three-dimensional schematic view of the shallow crust beneath the Lucky Strike volcano located along a segment of the Mid-Atlantic Ridge at ~37°18′N latitude. Colors indicate the P-wave velocity gradient structure. The thick red band, bounded by the dashed and solid gray lines, indicates the velocity jump at the base of layer 2A. The young shallow crust beneath the Lucky Strike volcano is interpreted as piled-up volcanic sequences emplaced within the axial valley. The volcanic units are shifted and rotated by normal faults. Reproduced from Arnulf AF, Harding AJ, Singh SC, Kent GM, and Crawford W (2012) Fine-scale velocity structure of upper oceanic crust from full waveform inversion of downward continued seismic reflection data at the Lucky Strike Volcano, Mid-Atlantic Ridge. *Geophysical Research Letters* 39: L08303. http://dx.doi.org/10.1029/2012GL051064.

where the axis of eruption is fairly narrow (~1–2 km), the formation of new crust can occur over the entire width of the axial valley (Barclay et al., 1998). Small, scattered velocity anomalies are commonly observed in 2D and 3D experiments and can arise from lateral variations in pores, cracks, alteration products, and the ratio of porous extrusive rocks to less-porous intrusive rocks and likely reflect the nonuniform construction of the upper crust with time. A detailed study of layer 2A beneath the Lucky Strike volcano on the MAR at 37°18′N shows low velocities and strong velocity gradients that are interpreted as piled-up volcanic sequences (**Figure 24**). In some areas, it is reported that upper crustal velocities are anomalously low in a broad axial band that parallels the ridge axis (e.g., Dunn et al., 2005; Magde et al., 2000; Seher et al., 2010b). Relatively low near-axis velocities with respect to higher off-axis velocities are a global phenomenon and widely interpreted to reflect a porous upper crust that decreases in porosity with age via hydrothermal deposition (**Figure 14**).

Along the axes of slow-spreading ridges, melt flux variations are thought to control crustal thickness, lithospheric strength, and the partitioning of plate spreading between magmatism and faulting (e.g., Cannat, 1993, 1996; Parsons et al., 2000; Tucholke and Lin, 1994). With higher melt supplies to many ridge segment centers (Blackman and Forsyth, 1989), seafloor spreading should be more magmatically accommodated near a segment's midsection and more tectonically accommodated at the ends (e.g., Cannat, 1993; Gràcia et al., 1999; Rabain et al., 2001; Tucholke and Lin, 1994). The great diversity of ridge segment morphologies and maximum depth of seismicity (e.g., Barclay et al., 2001), a proxy for lithospheric thickness, indicate that temporal variations in melt/heat supply modulate the magmatic–tectonic trade-off of crustal formation. Segment-to-segment diversity of ridge morphology can be interpreted as reflecting various stages of the magmatic–tectonic evolution (e.g., Barclay et al., 2001; Cannat, 1993; Gràcia et al., 1999; Singh et al., 2006a). Though even during magmatically robust periods, crustal magmatic systems are thought to be largely confined to segment centers.

At the ends of ridge segments, seismically observed thin crust and extensive upper crustal low-velocity regions, located both on-axis and off-axis, are likely the result of lower melt supply and a greater degree of tectonic stretching and fracturing. In support of this interpretation, geologic mapping of the seafloor (e.g., Gràcia et al., 1999) often reveals greater densities of cracks and fissures at segment ends than the segment center. Crust produced near segment ends may lack a distinct transition from seismic layer 2 to 3 (Canales et al., 2000a; Hosford et al., 2001; Sinha and Louden, 1983), and the transition from crustal to mantle velocities appears to occur over a depth range of 3 km or more (Canales et al., 2000a; Dunn et al., 2005). These seismic observations are consistent with a highly fractured and altered crust overlying a serpentinized upper mantle at segment ends.

A major characteristic that sets slow-spreading ridges apart from faster-spreading ridges is the exposure at the seafloor of lower crustal and mantle-derived ultramafic rocks. In many places, the crustal structure appears chaotic, with a thin or nonexistent seismic layer 3 and no consistent sheeted dike layer. Over the past 10 years, it has been recognized that extension by faulting, as opposed to extension accommodated by magmatic emplacement, is much more important than previously thought, accounting for over 50% of the extension along large sections of slow-spreading ridge (e.g., Buck et al., 2005; Cannat et al., 2006; Escartin et al., 2008; Olive et al., 2010; Smith et al., 2006, 2008; Tucholke et al., 1998, 2008). Detachment faults are common and can greatly disrupt the 'layer-cake' structure of the crust (**Figure 25**). Large, long-lived (>1 Ma) detachment faults with significant rotation expose extensive sections of the crust and upper mantle at the seafloor, forming what is known as an oceanic core complex (OCC). OCCs carry 50–100% of the plate separation velocity during periods when they are active (Grimes et al., 2008; Tucholke et al., 2008). They are often found at the inside corner of a ridge-transform intersection but can occur elsewhere along a spreading segment. There have been a number of seismic studies of individual OCCs and detachment faults, such as the Atlantis Bank at the SWIR (Henig et al., 2012; Muller et al., 2000), the Atlantis Massif at the MAR near 30° N (Blackman and Collins, 2010; Canales et al., 2004, 2008), the TAG area at the MAR near 26° N (Canales et al., 2007, 2008; de Martin et al., 2007), the Kane area at the MAR near 23°20′N (Canales, 2010; Canales et al., 2000b, 2008;

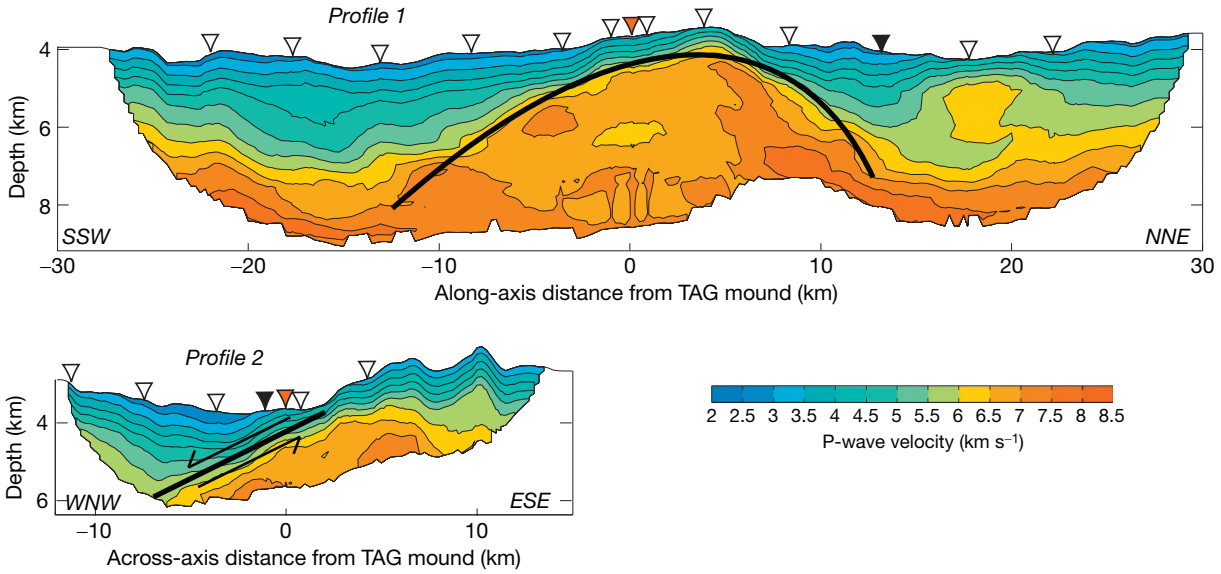

Figure 25 Seismic cross sections of the Mid-Atlantic Ridge via P-wave tomography. (Profile 1) Cross-section oriented parallel to the Mid-Atlantic Ridge and centered at ~26°10′N. (Profile 2) Cross-section oriented perpendicular to the axis of the ridge at 26°10′N. The thick black line in each profile indicates the (interpreted) geometry of the subsurface detachment fault. Red inverted triangle indicates the location of the TAG hydrothermal mound. Reproduced from Canales JP, Sohn RA, and deMartin BJ (2007) Crustal structure of the Trans-Atlantic Geotraverse (TAG) segment (Mid-Atlantic Ridge, 26°10′N): Implications for the nature of hydrothermal circulation and detachment faulting at slow spreading ridges. *Geochemistry Geophysics Geosystems* 8: Q08004. http://dx.doi.org/10.1029/2007GC001629.

Xu et al., 2009), the MAR 5° S (Planert et al., 2010), and the MAR 22°19′N (Dannowski et al., 2010). OCCs are often underlain by broad regions of anomalously high velocities at shallow depths and high vertical velocity gradients in the uppermost crust. Blackman et al. (2009) provide a review of geophysical studies of oceanic core complexes.

A limited number of seismic experiments have been performed to explore for crustal magma chambers along slow-spreading ridges. Refraction experiments located at 23°20′N (Canales et al., 2000b), 35° N (Dunn et al., 2005; Hooft et al., 2000), and 37° N (Seher et al., 2010b) on the MAR and 57°45′N on the Reykjanes Ridge (Navin et al., 1998) have detected significant low-velocity zones in the middle to lower crust, extending downward into the mantle, that are consistent with high temperatures and, in some cases, a small amount of melt. Reflection experiments have also detected shallow reflectors that indicate the presence of a shallow melt lens at the top of the broader magmatic systems (Singh et al., 2006a). However, the majority of these experiments were carried out in areas at least marginally affected by hot spots and thus may not be representative of slow-spreading ridge structure.

One seismically well-studied area of the MAR is the ~90 km long segment of the MAR at 35° N latitude, just south of the Oceanographer Fracture Zone. Several lines of evidence indicate that more melt is currently delivered to the center of this ridge segment than its ends. For example, an hourglass morphology and shallow water depth of the segment midpoint, an anomalously large mantle Bouguer gravity anomaly low-centered on the segment, and a chain of seamounts that intersects the segment center have all been attributed to enhanced magmatism near the segment center (Detrick et al., 1995; Rabain et al., 2001; Thibaud et al., 1998). This section of ridge may be mildly influenced by the Azores hot spot to the north and thus may exhibit slightly higher melt supply than for other non-hot spot-influenced sections of the ridge. At the center of the 35° N ridge segment, a large low-velocity 'plug' extends from about 4 km depth down into the mantle (**Figure 26**; Dunn et al., 2005). Assuming that the brittle–ductile transition is near 4 km depth, as indicated by the microearthquake study of Barclay et al. (2001), then the large low-velocity zone is most likely due to elevated temperatures and a small amount of melt (~3%) at depths >5 km. The melt could exist along grain-boundary interfaces or within larger isolated regions with higher melt concentrations, which, when averaged together, make up the 3% melt fraction. For example, the lower crust could be composed of partially molten dikes and sills. Dunn et al. (2005) detected seismic anisotropy within the large low-velocity region and suggested that this anisotropy and the reduced isotropic velocities are due to a cluster of vertical, partially molten, dikes in the lower crust. Crustal thickness studies for this area (Canales et al., 2000a; Dunn et al., 2005; Hooft et al., 2000; Hosford et al., 2001) reveal 8.5 ± 0.5 km thick crust near the segment center and 4–5 km thick crust to the north and south of center, with values as low as 3–4 km thickness (Hooft et al., 2000) near the Oceanographer Fracture Zone. Ridge-perpendicular variations in crustal thickness are modest, greater than or equal to ± 0.5 km in this area, which stands in sharp contrast to the 23°20′N area of the MAR, where the transition from crustal to mantle velocities undulates up and down with distance from the ridge, indicating that the magma supply waxes and wanes significantly with time (**Figure 27**; Canales et al., 2000b).

1.13.3.5 Ultraslow-Spreading Ridges

Mid-ocean ridges with ultraslow spreading rates, less than ~15–20 mm year^{-1} (full rate), include the SWIR and the

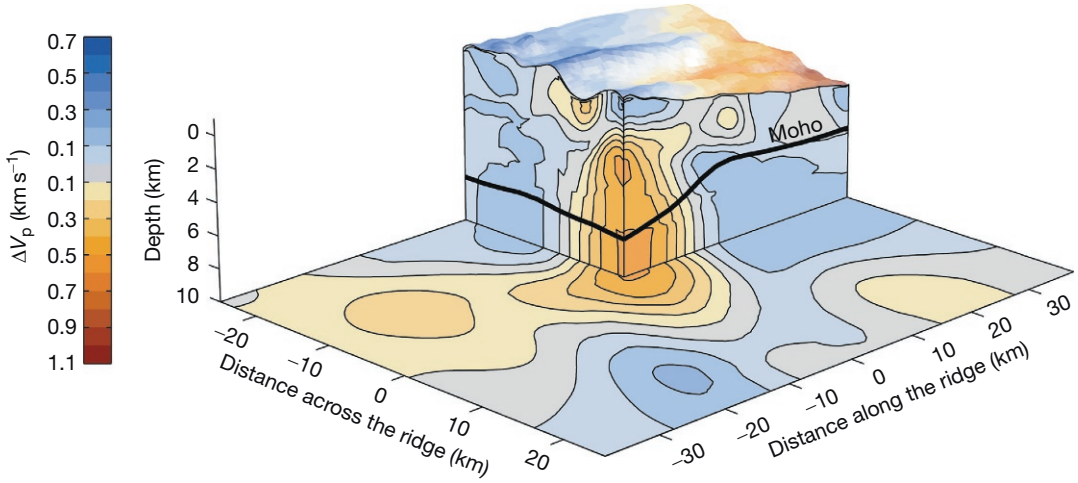

Figure 26 Three-dimensional perspective view of the P-wave velocity structure of the crust and mantle of the Mid-Atlantic Ridge at 35° N (relative to a 1D depth-dependent model). A low-velocity 'plug' is observed at the center of the ridge segment, where the crust is also up to 8.5 km thick (vs. <4–5 km thick near the segment ends). The velocity anomaly is consistent with high temperatures and a few percent melt and probably represents the current magma plumbing system for this section of the ridge. Seismic anisotropy in the lower crust at the segment center indicates that the anomaly is composed of a cluster of partially molten dikes that intruded from mantle depths. Reproduced from Dunn RA, Lekic V, Detrick RS, and Toomey DR (2005) Three-dimensional seismic structure of the Mid-Atlantic Ridge (35°N): Evidence for focused melt supply and lower crustal dike injection. *Journal of Geophysical Research* 110: B09101. http://dx.doi.org/10.1029/2004JB003473.

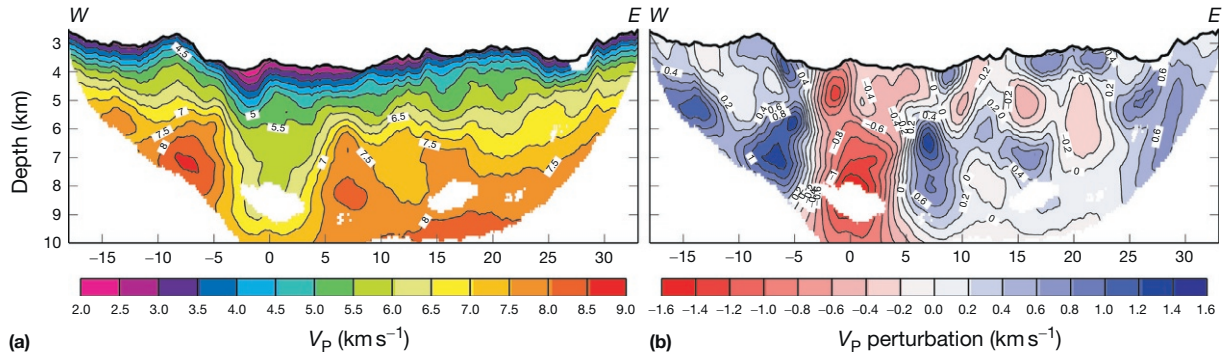

Figure 27 Two-dimensional tomographic images of the Mid-Atlantic Ridge near 23° N (MARK area). Plane of the images is perpendicular to the ridge axis. Anomalously low velocities beneath a neovolcanic ridge (near $x = 0$) extend downward from the middle crust and are consistent with high temperatures and 4% or more melt. Outside of this region, the crust is seismically very heterogeneous, with crustal thickness variations of >2.2 km over ~5 km distances. Such heterogeneity suggests that the melt supply fluctuates substantially over short timescales, creating periods of magmatic and amagmatic spreading. Reproduced from Canales JP, Collins JA, Escartin J, and Detrick RS (2000) Seismic structure across the rift valley of the Mid-Atlantic Ridge at 23°20′N (MARK area): Implications for crustal accretion processes at slow spreading ridges. *Journal of Geophysical Research* 105(B12): 28411–28425.

ridges that lie north of the Arctic Circle: the Mohns, Knipovich, Molloy, and Gakkel Ridges (Figure 1). Ridges in this category display a lack of transform faults and are instead composed of linked magmatic and amagmatic accretionary segments of ridge (Dick et al., 2003). A critical issue is how an exceptionally slow spreading rate influences melt production, crust and lithosphere thickness, tectonics, volcanism, and many other ridge processes. To date, several seismic refraction profiles near these ridges have been carried out, but they generally have sparse station spacing (spacing > crustal thickness) and are sometimes not reversed (with seismic energy traveling in opposite directions) such that their interpretation can be ambiguous. There have been no large and dense 3D refraction or multichannel reflection studies of an ultraslow-spreading ridge to date (there is one as yet unpublished 3D study along the SWIR (Jian et al., 2012)). The details of crustal and lithospheric formation along these ridges are consequently less well understood.

While crustal thicknesses for these ridges are often quoted to decrease with spreading rate from roughly 4 to 0 km (Figure 10), when each ridge is examined individually, we see that seismically determined values of crustal thickness vary widely and crustal thickness does not decrease uniformly with spreading rate. Instead, episodic and spatial variations in melt supply appear to govern crustal thickness, with values reported in some areas that exceed the global average thickness (e.g., Jian et al., 2012), and in other areas mantle, rocks are

found on the seafloor (Michael et al., 2003). Ridge-parallel refraction profiles at different lithospheric ages along the central portion of the Mohns Ridge provide estimates of crustal thickness between 3.75 and 4.5 km, with $1-\sigma$ uncertainties of 0.3–1 km, depending on the profile (Klingelhöfer et al., 2000). Profiles extending away from the Knipovich Ridge reveal crustal thicknesses of 3.5–5.6 km at the ridge, though values as high as 8 km are found away from the ridge axis (Ljones et al., 2004; Ritzmann et al., 2002). A seismic profile extending away from the Molloy Ridge reveals a thickness of ~4–5 km near the ridge, ~3 km near the Molloy Fracture Zone, and values as high as 10 km away from the ridge axis (Czuba et al., 2005). Nonreversed seismic profiles collected along the Gakkel Ridge resulted in crustal thickness estimates of 1.2–3.5 km (Jackson et al., 1982; Jokat and Schmidt-Aursch, 2007). Along the SWIR, crustal thickness estimates range from 2 to 2.5 km beneath the ridge segment boundaries to values of 3.5–6 km at segment midpoints (Muller et al., 1997, 1999).

Seismic studies show that the basic velocity structure, as a function of depth, differs greatly from that observed at faster-spreading ridges (e.g., **Figure 12**). While a seismic layer 2 is often present, seismic layer 3 tends to thin as crustal thickness decreases and P-wave velocities of the lower crust are less likely to exceed 6.5 km s^{-1}. Mantle velocity values are also found to be generally low both beneath the ridges and in off-axis areas (e.g., Klingelhöfer et al., 2000), and there has been considerable debate as to whether these low values are due to high temperatures and melt, the effect of anisotropy (for profiles not oriented in the spreading direction), mantle serpentinization (due to increased faulting along these ridges), melt retention (due to freezing in of melt as it rises beneath a cold spreading center – see also **Section 1.13.2.5**), or a combination of factors.

1.13.3.6 Regional Influences

Sections of mid-ocean ridge located near hot spots have long been recognized to be influenced by these mantle anomalies (Schilling, 1985; Vogt, 1976). These include the Galápagos Spreading Center (Galápagos hot spot), Mid-Atlantic Ridge (Iceland, Azores, and Tristan da Cunha hot spots), Juan de Fuca Ridge (Cobb hot spot), Mohns Ridge (Jan Mayen hot spot), Southwest Indian Ridge (Marion and Bouvet hot spots), and Southeast Indian Ridge (Amsterdam – Saint Paul hot spot), among others (e.g., Courtillot et al., 2003). Hot spots may produce a large regional-scale thermal anomaly that underlies the ridge, perhaps linked to excess temperatures produced in the upper mantle by a deep-seated plume. Hot spots may also provide lateral flow of plume material along, and across, the ridge axis (e.g., Morgan, 1978; Schilling, 1991; Vogt, 1976). Generally speaking, at ridges influenced by hot spots, melt production is enhanced, the crust is thicker than the global average of 6–7 km, the ridge axis is hotter (the lithosphere is thinner), and long-lived crustal magma chambers may be present. One exception is crust formed in the Wharton Basin, where a fast-spreading-rate ridge produced anomalously thin crust (Singh et al., 2011). The authors of this study suggest that a thick layer of cold lithosphere surrounding the Kerguelen plume suppressed mantle melting beneath the ridge. In addition, regional mantle thermal anomalies not of hot spot origin may influence ridge processes. Along the Southeast Indian Ridge, the ridge axis deepens and the crust thins toward the Australian–Antarctic Discordance (Holmes et al., 2008), an area that has been suggested to be a mantle 'cold spot.' Many small mantle chemical anomalies may also influence subridge melting and ridge properties.

The Iceland anomaly is the largest of the ridge-related hot spots. Seismic surveys to the south of Iceland along the Reykjanes Ridge portion of the MAR have found evidence for thick crust (Smallwood et al., 1995) and a shallow melt lens capping a crustal magmatic system (Navin et al., 1998; Peirce et al., 2005; Sinha et al., 1997). A higher melt supply results in hotter axial temperatures and a weaker axial lithosphere. Crust produced along the Reykjanes Ridge is anomalously thick to a distance of ~1000 km from Iceland. To the north of Iceland, along the Kolbeinsey Ridge, seismic refraction profiles also reveal anomalously thick crust as well as evidence for high crustal temperatures and perhaps melt beneath the ridge axis (Hooft et al., 2006; Kodaira et al., 1997).

A seismic survey of the MAR south of the Azores islands, located on the bathymetric swell of this hot spot, has also detected a shallow crustal melt lens (Singh et al., 2006a) and underlying low-velocity zone (Seher et al., 2010a). In this case, a reflection from the top of the melt lens, centered beneath the Lucky Strike volcano and hydrothermal field, is ~3 km beneath the seafloor, 3–4 km wide (much wider than the average along the EPR), and extends up to 7 km along the ridge. The colocation of the melt lens and active hydrothermal field indicates that the lens provides the heat that drives the hydrothermal circulation (Singh et al., 2006a). The broader magmatic system, as indicated by the low-velocity zone, is colocated with relatively thick crust (Seher et al., 2010a).

1.13.3.7 Back-Arc Spreading Centers

From observations made to date, the basic structure of oceanic crust and lithosphere formed in back-arc settings appears to be rather different, and perhaps more complex, than the crust formed along mid-ocean ridges. While the spreading rate is a dominant factor that controls crust and lithospheric structure of normal ridges, in back-arc settings, slab-derived volatiles – principally water – appear to have a large control on melting processes and crustal formation that can overcome spreading rate trends. The presence of water during melting is expected to enhance melt production (e.g., Davies and Bickle, 1991; Stolper and Newman, 1994), with the water ending up in the melt (e.g., Hirth and Kohlstedt, 1996), and may also lead to more silicic lavas (e.g., Gaetani et al., 1994; Nicholls and Ringwood, 1973; Sisson and Grove, 1993).

One major observation is that when a back-arc spreading ridge is located close to an active arc system, the magma supply to the ridge appears to be relatively high and lavas erupted at the ridge have high water contents, with compositions ranging from basalts to rhyolites. In addition, the thermal structure of the ridge appears to be more like mid-ocean ridges with fast spreading rates, even though the back-arc spreading rate might be quite slow. For example, the presence of a dome-shaped ridge and a shallow magma lens is often considered an indication of high melt supply from the mantle and a hotter ridge

axis. Domed ridges and crustal magmatic systems have been found along intermediate to slow-spreading ridges in back-arc settings, including of the Valu Fa Ridge (Collier and Sinha, 1992; Jacobs et al., 2007; Turner et al., 1999), the East Scotia Ridge (Livermore et al., 1997), and the Malaguana–Gadao Ridge (Becker et al., 2010).

The Valu Fa Ridge, the southern portion of the Lau spreading center, is situated only 40 km from the active arc, and its domed ridge is underlain by a shallow melt lens (Collier and Sinha, 1992; Jacobs et al., 2007). Lavas have compositions of andesitic basalts, andesites, and rhyolites (Frenzel et al., 1990) with high volatile contents: >1 wt% H_2O and 0.03 wt% CO_2 (Michael et al., 2011; Vallier et al., 1991). Segment E2 of the East Scotia Ridge, located close to the arc system, has an 'inflated' morphology and a shallow melt lens reflector (Leat et al., 2000; Livermore et al., 1997) and erupts basalts with 0.77–1.02 wt% H_2O (Fretzdorff et al., 2002). The Malaguana–Gadao Ridge is located behind the Mariana subduction zone, in the southern portion of the basin and near the active arc. It also exhibits an inflated axial summit and shallow melt lens reflector, though of limited along-axis extent (Becker et al., 2010). No direct observations of lava chemistry are yet available at this location. These results, taken together with other data, indicate that ridges located close to active arcs either directly entrain arc melts into their upwelling systems or entrain hydrated mantle into their upwelling zone that subsequently leads to greater extents of melting.

Along the Lau spreading center in general, as the ridge becomes closer to the arc to the south, the spreading rate decreases, seismic layer 2A thickens from 0.4 to 1.0 km, near-seafloor P-wave velocities decrease from 2.1 to 1.8 km s^{-1}, and the velocities of both layers 2A and 2B decrease from 3.2 to 2.5 and 5.0 to 3.9 km s^{-1}, respectively (Jacobs et al., 2007). These observations are consistent with increased volatile concentration and more felsic compositions of magmas to the south as the ridge approaches the arc.

In 2009, a 3D tomography experiment was carried out along the Eastern Lau Spreading Center within the Lau basin (Arai and Dunn, 2014; Dunn and Martinez, 2011; Dunn et al., 2013). The largest of its kind, the experiment covered a total area of 8000 km^2 and revealed large systematic changes in seismic velocity of the upper crustal volcanic layer. In plan view, the crust formed at the Eastern Lau Spreading Center is characterized by distinct zones of relatively low, intermediate, and high compressional wave velocities (**Figure 28**) that are most likely related to variations in both bulk rock porosity and composition. The velocity variations spatially correlate with estimates of crustal thickness changes, major element changes in seafloor lavas, geochemical estimates of changes in source volatile content (and other arc-related components), and changes in the vesicularity of seafloor samples.

The seismic structure, via the effects of crustal porosity and composition, provides a record of changes in the initial volatile content of melts fed to the ridge. The results indicate that when

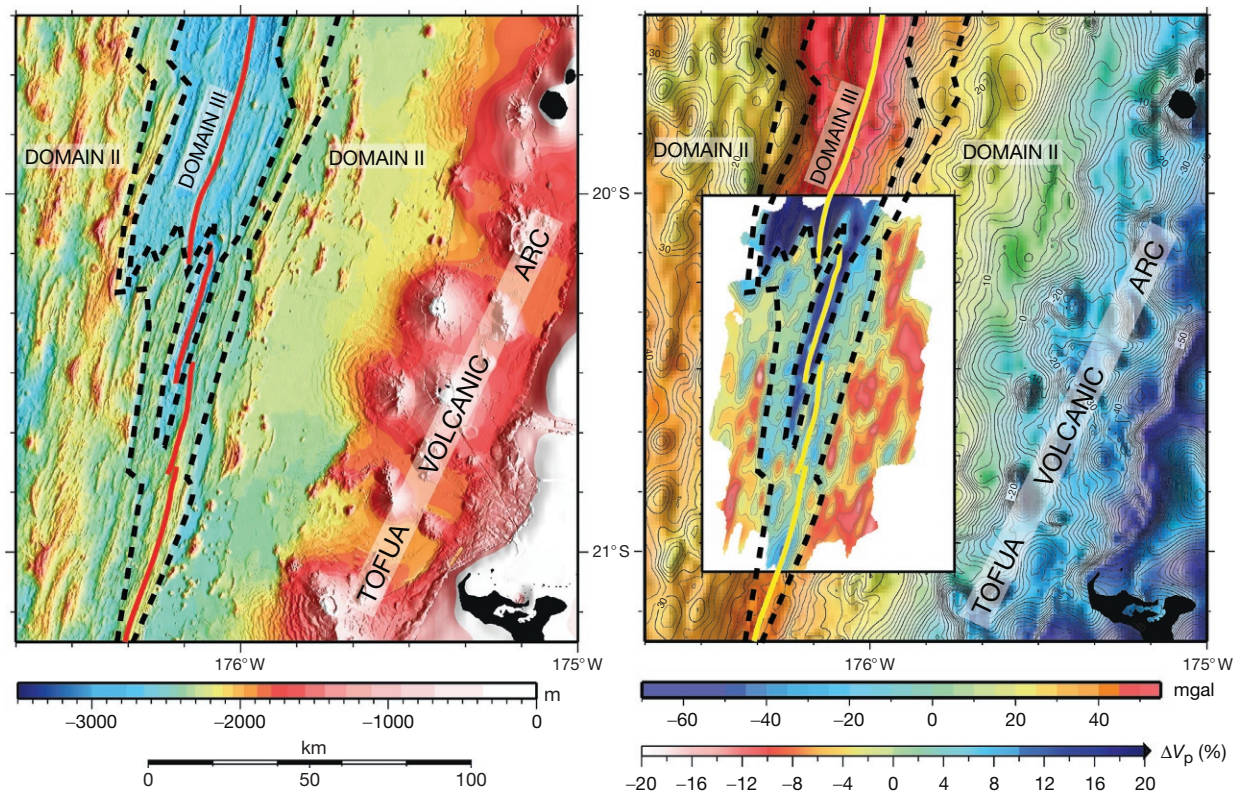

Figure 28 (Left) Lau basin bathymetry showing the Eastern Lau Spreading Center (red line), the active Tofua volcanic arc, and labeled crustal domains demarcated by dashed lines. (Right) Lau basin Bouguer gravity and crustal domains. Inset shows upper crustal P-wave seismic wave speed. Regions of low velocity correspond to regions of thicker, shallower relief, crust, relatively lower gravity, and occur in crust that originally formed closer to the arc. Results from Dunn and Martinez (2011).

the ridge was closer to the arc, water in the mantle led to a greater extent of melting and high-water-content lavas. As the basin opened and the ridge migrated away from the arc, the entrainment of this water was abruptly cut off, and the ridge transitioned to creating a thinner crust with volatile poorer lavas. In the spreading direction, observed steplike transitions between these domains suggest that abrupt changes in mantle source composition take place over as little as 5 km of incremental spreading.

In back-arc settings, there have been few measurements of lower crustal and mantle velocities or crustal thickness. A single, dense, seismic refraction profile across the central portion of the Mariana Trough (Takahashi et al., 2009) reveals a crustal structure that can be described by three principal layers: a shallow layer with V_p of 3.3–5.6 km s^{-1}, a central 5.4–6.1 km s^{-1} layer, and a lower crustal layer of 7.1–7.4 km s^{-1}. Crustal thickness is mostly 5–6 km, and the mantle V_p is 7.8–8.0 km s^{-1}, with the lowest values beneath the spreading center. Crustal velocities are also anomalously low beneath the spreading center, suggesting high crustal temperatures and perhaps melt.

In crust formed along normal mid-ocean ridges, P-wave velocities greater than ~7.1 km s^{-1} are rarely observed via modern seismic experiments. On the other hand, high-velocity lower crust, 7.1–7.6 km s^{-1}, is often found along arc systems (e.g., Kodaira et al., 2008; Takahashi et al., 2009) and is usually considered to be of igneous origin (gabbroic rocks rather than serpentinized mantle). In the Mariana back arc, crust with a high-velocity lower layer was created at the spreading center. Additionally, a high-velocity lower layer (7.1–7.6 km s^{-1}) has been detected in the Lau basin in broad regions of crust that formed at the spreading center when it was located near the active volcanic arc (Arai and Dunn, 2014). The origin of these high-velocity layers is as yet unknown but may be related to specific P–T and compositional conditions particular to the region above the subducting slab. One hypothesis is that they are the result of hydrous fractional crystallization in the crust (Gaetani et al., 1994; Sisson and Grove, 1993), wherein water in the melt suppresses early plagioclase formation, producing a more ultramafic lower crust (of higher than usual velocity) and consequently a more felsic upper crust (of lower than usual velocity; Arai and Dunn, 2014).

1.13.4 Remaining Unsolved Problems

Despite significant progress, many of the fundamental processes occurring at mid-ocean ridges and back-arc systems remain poorly understood. There are many questions remaining about the form of mantle upwelling at shallow levels and the mechanism of melt transport. For example, the focusing of melt from a wide melting zone at depth (>100 km) to a narrow neovolcanic zone at the ridge axis (1–2 km) remains unexplained. Along slow-spreading ridges, we still do not know to what extent variations in crustal thickness at the segment scale are caused by diapiric upwelling versus focused melt migration. At ultraslow spreading rates, the depth extent of cooling from above is unknown, as well as the degree of melting and the amount of melt that is generated but never leaves the mantle. A question raised by the teleseismic studies of regional and global structure is whether there is anisotropy associated with mid-ocean ridges extending to depths of 300 km or more, as suggested by the discrepancy between Love and Rayleigh wave images of the mantle. If this apparent anisotropy is real, it has profound implications for the pattern of overall flow in the oceanic mantle. The procedures and assumptions leading to this conclusion need to be carefully examined. In back-arc settings, the relationship between the ridge upwelling zone, its melting zone, subarc melting, and overall wedge flow is only vaguely understood.

At crustal levels, we observe large variations in accretionary style for ridges of different spreading rates. As spreading rate drops, the nature of ridge segmentation changes, magma supply becomes more intermittent, and spreading is partitioned into periods of tectonic stretching versus magmatic accretion. To first order, ridge thermal structure is difficult to establish, leading to much uncertainty. For example, the formation and cooling of the lower crust is strongly debated, and along slow-spreading ridges, the idea that spreading is portioned into regions or times of magmatic accretion versus faulting and tectonic stretching is well established but poorly documented.

Limited global sampling of mid-ocean ridges and back-arc spreading systems leads to observational biases. While fast-spreading ridges have been extensively studied as compared to slower-spreading ridges, fast-spreading ridges comprise only 10% of the global ridge system (**Figure 2**). Along slower-spreading ridges, many studies tend to focus on more magmatically robust segments of ridge, especially near hot spots, and thus, we still do not have a good understanding of the average thickness of crust produced along these ridges. In addition to this selection bias, it is possible that true crustal thickness is masked by mantle serpentinization, which gives crust-like velocities to the mantle. The presence or absence of magmatic systems along non-hot spot-influenced sections of slow-spreading ridges is often inferred indirectly, but not determined by direct seismic observation.

At the ridge segment scale, we need higher-resolution 3D images of both the crust and the uppermost mantle to answer these basic questions. A major problem is the lack of studies at scales intermediate between global tomography and small, local seismic reflection and refraction experiments. If we are to understand the processes occurring along the global mid-ocean ridge system, a number of dense ocean-bottom seismic studies must be carried out. Land-based stations are insufficient for examining the Earth's structure beneath the ridges. Body waves recorded by such stations have poor coverage and resolution in the oceans. In addition, the sensitivity zone for surface waves widens with path length (Spetzler and Snieder, 2001; Yoshizawa and Kennett, 2002), meaning that even with good path density and azimuthal coverage, the use of long propagation paths limits the lateral resolution of surface-wave images. Instead, denser broadband arrays must be deployed to record shorter-ray-path, higher-frequency, teleseismic, and regional data. Active-source experiments must be scaled up to cover larger regions in a denser fashion. In the future, some of the biggest gains will be achieved by simply increasing the number of instruments deployed on the seafloor.

1.14.1 Introduction to Hot Spots

Hot spots, defined as volcanic regions unrelated to standard plate boundary processes such as plate separation or subduction, are widespread on the surface of the Earth ranging from the polar regions (e.g., Mount Erebus in Antarctica) to the tropics (**Figure 1**). Hot spots are found on both continents and in ocean basins. They are responsible for transporting about 10% of the planetary heat flux from the interior to the surface (Davies, 1988). Geologic evidence suggests that hot spots have been cooling this planet and contributing to its chemical differentiation since the Archean (Burke and Dewey, 1973; Ernst and Buchan, 2003). Our nearest neighbors, Venus and Mars, both have surface features created by hot-spot-like volcanism (Ernst et al., 2001; Head et al., 1992; Smith et al., 1999), even though neither of these two planets shows any clear signs of plate tectonics at present or in the discernible geologic past (Solomon et al., 1992). The most volcanically active body in our solar system is a moon of Jupiter, Io. Clearly, hot-spot volcanism is a process important to the evolution of terrestrial planets, and can cool a rocky planet under rheological conditions that are not conducive to plate tectonics (**Table 1**).

1.14.1.1 Origin of the Hot-Spot Concept

The scientific study of hot spots, through the oceanic islands they produce, is more than 200 years old, even though the term 'hot spot' itself is quite recent. Charles Darwin, as a result of observations made in the course of his voyage on the HMS Beagle in 1835, noted that there were only three types of islands: volcanic, coral, and combinations of the two. (This was clearly a simplification, as it ignored islands that rest on continental foundations, such as the Seychelles.) He proposed (Darwin, 1842) that magma erupts in copious quantities from vents in the seafloor to form high volcanic islands, and then the magma source dies. In favorable locations, coral reefs begin to grow on the fringes of the shorelines as the volcano subsides. Eventually, the original volcano is completely submerged beneath the waves, leaving a circular coral atoll with a central lagoon marking the location of the former volcano (**Figure 2**). Embodied in Darwin's simple hypothesis were the concepts that the eruptions that give rise to oceanic islands have a rather finite lifetime and that the islands gradually subside. It would be more than 100 years until scientists had enough information on the deep sea to begin to explain these essential phenomena.

The American geologist James Dwight Dana was the first American geologist to visit the Pacific islands in 1839, and was already aware of Darwin's hypothesis. After 3 months in the Hawaiian Islands, Dana correctly surmised from the geomorphologic degree of erosion that the islands become progressively older to the northwest (**Figure 3**), quite a feat of scientific deduction at a time when few scientists accepted the idea that valleys are eroded by the streams that cut through them (Menard, 1986). Dana, having visited other chains of

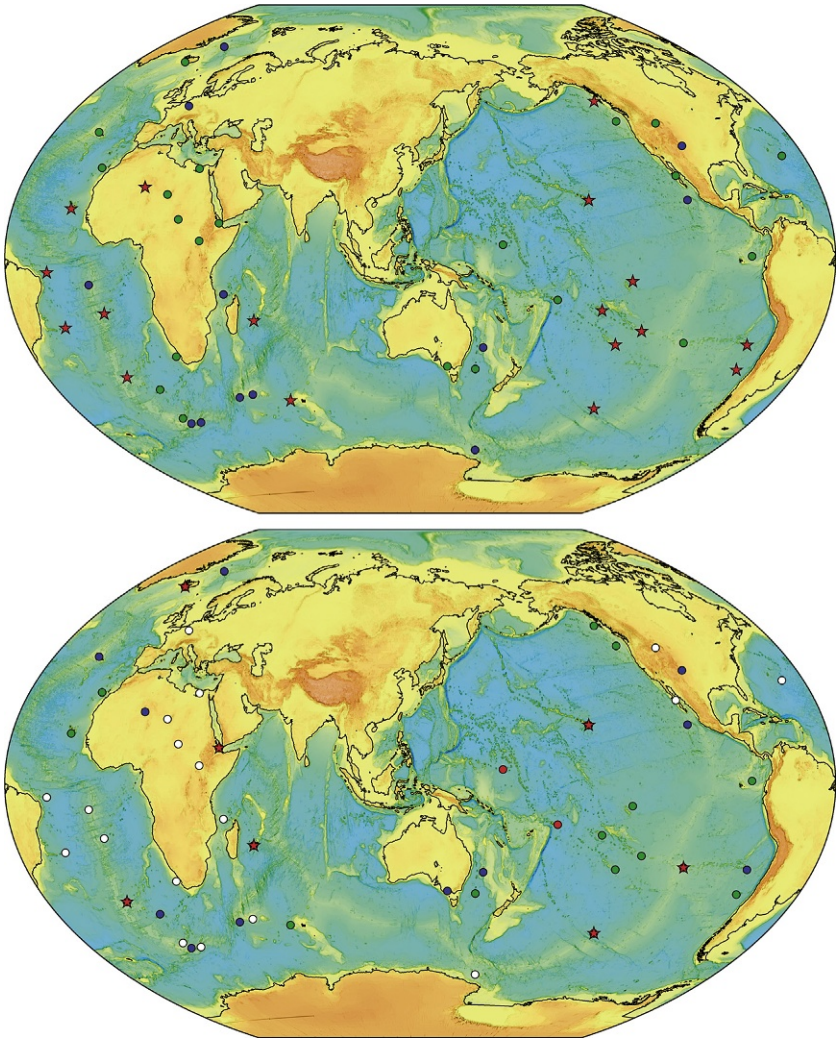

Figure 1 Map showing locations of proposed hot spots listed in **Table 1**. Top: Hot spots listed in the catalogs of Davies, 1988; Sleep, 1990, and Steinberger, 2000. Hot spots indicated in red are common to all three catalogs. Those in green appear in two of the three sources, and those in blue are listed only once. Bottom: Proposed hot spots analyzed by Courtillot et al. (2003). Courtillot et al. (2003) consider five criteria aimed at detecting hot-spot volcanism associated with deep-mantle plumes. The seven hot spots meeting three or more of the criteria are shown in red. Those satisfying two criteria are shown in green, one criteria in blue, and none of the criteria in white.

volcanoes in the Pacific, such as Society Islands, generalized his model to conclude that Pacific islands form chains that are oriented, and increase in age, to the northwest.

Dana's simple generalization was dismissed or forgotten as improved soundings of the depths of the oceans brought about by the development of echo sounders revealed much older lines of volcanoes with different orientations, such as the Emperor Seamount chain, or with confused orientation, such as the Mid-Pacific Mountains. By using a selective 'eye' to the evidence, Chubb (1957) reaffirmed Dana's hypothesis that nearly all of the high islands in the central and western Pacific trend to the west-northwest, and went on to propose that their older extension, now sunken guyots, trended to the north-northwest. He concluded that "the direction of earth movements" had changed over geologic time.

Soon after, Harry Hess of Princeton University came up with an explanation for (at least a portion of) the subsidence of oceanic islands as hypothesized by Darwin. As a naval officer during World War II, Hess had collected better records of seafloor depths in the Pacific Ocean than had ever before been available. He proposed (Hess, 1962) that new oceanic crust is created at mid-ocean rises (ridges in modern parlance), from whence it is passively carried laterally and downward by convection currents to sinks at oceanic trenches. Robert Dietz termed this process 'seafloor spreading' (Dietz, 1961). The vertical motion of the seafloor as it spreads laterally away from the mid-ocean ridges was soon after explained both physically and mathematically as the conductive cooling of a thermal boundary layer (Turcotte and Oxburgh, 1967) or plate (McKenzie, 1967). Simple thermal contraction of the seafloor as it ages results in nearly a 4 km depth difference between the mid-ocean ridges and the >100 Ma deep-sea basins as depth increases as the square root of age. Thus Darwin's islands were subsiding because the entire seafloor

The second column indicates by X (listed) or O (not listed) whether each candidate site was included in the hot-spot catalogs of Davies, 1988, Sleep, 1990, and Steinberger, 2000, respectively. The second column shading corresponds with the number of listings; the darkened sites are listed in all three catalogs. The third column indicates how many of the five deep-plume criteria considered by Courtillot et al. (2003) each proposed hot spot satisfies (? indicates an additional criteria possibly satisfied). The seven hot spots listed in bold type are considered likely to be of deep plume origin by Courtillot et al. (2003).

beneath them was subsiding as it ages on its route to a site of crustal recycling.

J. Tuzo Wilson, building on the Hess and Dietz concept of seafloor spreading, suggested that the seafloor is carried along on a great convective conveyor belt. He envisioned that the stagnant center could be the source of lava that would rise to form an age-progressive chain of volcanoes (**Figure 2**), like Hawaii (Wilson, 1963). The difficulty with this concept is that many such chains of volcanoes are not located in or even near the centers of the plates.

Morgan (1971) and Morgan (1972) applied plate tectonic theory to the major island chains, introducing the concept of deep-mantle plumes as the source for age-progressive chains of volcanoes. Morgan demonstrated that many linear island chains could be modeled as a trace on a moving tectonic plate of a fixed position in the underlying, assumed stationary mantle. According to Morgan's hypothesis, instabilities develop on boundary layers as deep as the core–mantle boundary (CMB). These instabilities cause hot, buoyant material to detach in jet-like filaments from the thermal boundary layer and ascend relatively rapidly to the Earth's surface, transporting both mass and heat. Steady movement of the plate over these relatively stationary 'plumes' would give rise to an age-progressive chain of volcanoes, such as the Hawaiian Islands (**Figure 4**). Plume theory was thus able to account for Darwin's observation of a geologically brief period of eruptive activity for any one volcano and Dana's observation of a monotonic progression in degree of erosion.

In addition to the anomalously high rates of basaltic volcanism, hot spots are also typically associated with hot-spot swells (Dietz and Menard, 1953). These features are broad (~500 km across), high (~500–1000 m) domes that surround the region of active volcanism. Atlantic swells tend to be circular in planform (e.g., Bermuda, Cape Verde), while Pacific swells are elongated at the young end of the hot-spot chain (Society). The Hawaiian swell is particularly prominent and forms a tear-drop shape with the tail pointing to the west-northwest (**Figure 5**).

Although hot spots and hot-spot swells are found both on continents and in the ocean basins, this review focuses on the latter. Contrary to the case for continental settings, there exist baseline models for oceanic lithosphere setting the normal standards for key geophysical parameters such as elevation of Earth's surface, crustal thickness, elastic plate thickness, and seismic velocity structure. Much has been learned about the processes which give rise to this kind of volcanic activity by comparing the observations against these standard models.

In this chapter, we will use the term 'hot spot' in the purely descriptive sense to mean a region that has experienced an unusual volume of volcanic activity that is unrelated to plate boundary processes, without any assumption of the underlying cause for that activity. For example, in the case of mid-ocean ridges, material that passively rises to the surface in the gap between diverging plates cools on account of pressure release and expansion at the rate of 0.3 °C km^{-1}, while the temperature at which melting occurs drops at the rate of 3 °C km^{-1} as the surface is approached. This leads to a melting zone several tens of kilometers thick near Earth's surface beneath the mid-ocean ridge where the temperature of the rising mantle

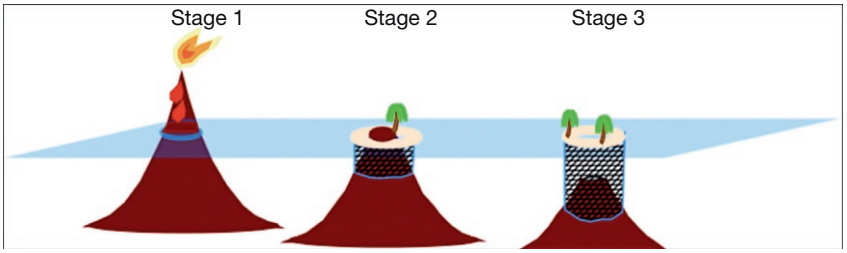

Figure 2 Cartoon showing the geologic progression of volcanic islands as proposed by Darwin. In stage 1, a volcano grows above the seafloor to form a high island during the active eruption phase. In stage 2, the inactive volcano is eroded and subsides to form a low island surrounded by a fringing reef. In stage 3, the volcano sinks entirely beneath the waves as the coral reef continues to grow upward to maintain its surface at sea level.

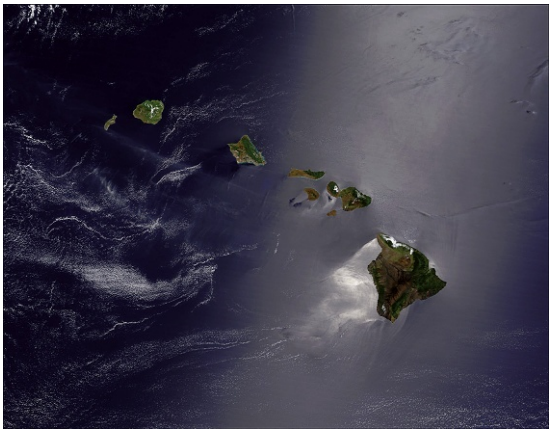

Figure 3 Terra MODIS image of the Hawaiian Islands, illustrating the progressive degree of wave-cut and stream erosion for islands further to the northwest, as first documented by Dana. From the southeast to the northwest, the islands are Hawaii, Maui, Kahoolawe, Lanai, Molokai, Oahu, Kauai, and Niihau. Even older volcanoes lie further to the northwest, most of which are entirely submerged.

material is above its melting point. The net thickness of crust produced under these conditions is about 6 km. At hot spots, the crust is thickened beyond that nominal 6 km. There are at least three obvious ways to create more melt and thus thicken the crust: invoke some geodynamic process other than plate spreading to move more material vertically through the melting zone, add heat, or reduce the temperature at which melting occurs (by, e.g., adding fluids into the melt zone; Bonatti, 1990). Thus 'hot spots' need not be hot. Even when melting is caused by the addition of heat, it need not be internal in origin; for example, tidal friction caused by gravitational interactions with Jupiter, Europa, and Ganymede is suspected to be the cause of volcanism on Io (Spencer and Schneider, 1996). The fact that there are a number of ways to create the most obvious indication of a hot spot, thickened crust, has placed added importance on the use of other geophysical observations, such as seismology, to help determine the cause of melting.

In this chapter, we will not use the terms 'hot spot' and 'plume' interchangeably. Hot spots as a geologic phenomenon clearly exist. The debate is still ongoing as to which ones, if any, might be attributed to mantle plumes.

1.14.1.2 Potential Significance of Hot Spots

With Morgan's elegant hypothesis that deep-mantle plumes produced age-progressive island chains on the surface of lithospheric plates, geophysicists and geochemists immediately seized upon the potential for the study of hot spots to increase our understanding of the planet. First, it was hoped that the deep-mantle plumes might provide a fixed reference frame from which the absolute motions of the plates could be determined (Duncan, 1981; Gordon and Jurdy, 1986; Molnar and Stock, 1987). Second, the lavas erupted from the volcanoes created by the plumes might provide samples of and potentially define distinct rock reservoirs in Earth's deep mantle (Zindler and Hart, 1986). Third, an intriguing correlation between continental breakup and the initiation of plumes suggested that they might be a powerful force to rearrange the tectonic plates (Storey, 1995). More speculatively, changes in the flux from plumes through time could be the explanation for changes in sea level (Pitman, 1978), mass extinction events (Vogt, 1972), and geomagnetic superchrons (Larson and Olsen, 1991). Correlations between hot-spot activity and impact histories for the Moon and Earth led Abbott and Isley (2002) to suggest that hot spots might even be triggered by extraterrestrial impacts. With hot spots being the most obvious geologic phenomenon of internal origin that is not a direct consequence of plate tectonics, the general hope was that their study would reveal secrets about the interior of the planet otherwise masked by the rigidity of the surface tectonic plates.

In the last 40 years, plate tectonic theory has found complete acceptance in the scientific community. As new ways to probe the plates were devised, disparate bits of evidence were in agreement with the main tenants of the theory. After only a decade or so, the main research to address questions in plate tectonics was already in the phase of cleaning up loose ends and filling in details. In contrast, in that same 40 years, the existence of deep-mantle plumes as the explanation for hot spots has become even more mired in controversy. The predictions of plume theory are borne out for very few hot spots, and there is concern that in those few cases the reasoning is almost circular. For example, indeed the orientation and age progression on the Hawaiian chain match the model predictions for absolute motion of the Pacific Plate over a fixed mantle plume, but the absolute direction and rate of drift of the Pacific Plate was derived assuming that the Hawaiian chain records the motion of the plate over a fixed mantle plume! Even Morgan himself, early on, recognized that plume theory

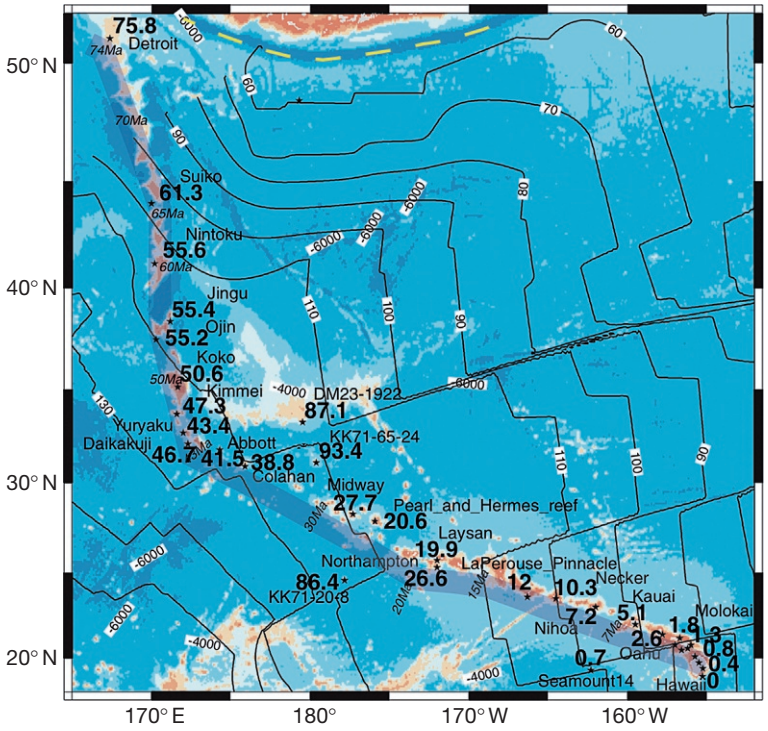

Figure 4 Volcanic age progression along the Hawaiian–Emperor seamount chain in the north Pacific. Mean ages of the seamounts in Ma. The stars represent the locations of the seamounts as determined from radiometric dating of rock samples. Crustal magnetic isochrons are represented every 10 Ma by thin black lines. The seamount ages increase monotonically to the northwest. The bend in the seamount chain about 50 Ma corresponds to a shift in Pacific Plate motion (Sharp and Clague, 2006). Reproduced from Clouard V and Bonneville A (2005) Ages of seamounts, islands and plateaus on the Pacific Plate. In: Foulger GR, Natland JH, Presnall D, and Anderson DL (eds.) *Geological Society of America Special Paper 388: Plates, Plumes & Paradigms*, pp. 71–90. Boulder, CO: Geological Society of America.

was unlikely to explain all hot spots (Morgan, 1978). There is no complete agreement even on how many hot spots there are now and in the recent geologic past (Davies, 1988; Sleep, 1990; Steinberger, 2000).

To be fair, some of the original expectations for the predictive power of plume theory were based on limited understanding of the properties in Earth's interior, and still are. For example, even if all hot spots are caused by plumes, it would never be possible for any set of global plumes to provide a fixed mantle reference frame on account of large-scale, time-dependent convection in the mantle (Steinberger and O'Connell, 1998). To this date, debate continues on the nature of thermal boundary layers deep within this planet, on the scales of geochemical heterogeneity, and the interpretation of isotopic arrays (Phipps Morgan, 1999). More detailed and more sophisticated analysis of seismic data with resolving power below the transition zone (Montelli et al., 2004; Ritsema and Allen, 2003) holds the promise for advancing understanding in these areas.

1.14.2 Types of Hot Spots

Young, high volcanoes actively erupting in mid-plate settings were the first manifestation of hot-spot volcanism to be so recognized. As the ocean basins were more thoroughly explored, several other categories of hot-spot activity became apparent based on their distinct morphology, including aseismic ridges (Laughton et al., 1970), superswells (McNutt and Fischer, 1987), and large igneous provinces (LIPs) (Coffin and Eldholm, 1994). The latter category has been interpreted to include all of the former types of hot-spot activity, but in this chapter we will use the term in the more narrow sense to refer to voluminous flood basalts that erupt quickly over a large area (sometimes called 'transient LIPs').

1.14.2.1 Large Igneous Provinces

Both continents and ocean basins contain examples of large-volume flood basalts covering areas of 10^5 km^2 or more that erupted in time periods of the order of 1 My (Coffin and Eldholm, 1994). On the continents, these events are preserved in the thick basalt formations of the Deccan Traps, the Siberian Traps, and numerous other formations spanning the geologic ages. On the ocean floor, these types of eruptions form large submarine plateaus such as Ontong Java and Kerguelen. This category of hot-spot activity forms LIPs, the class of hot-spot-type volcanism that can rival the mid-ocean ridge system for crustal production during bursts of intense activity (**Figures 6** and 7) and the form most likely to have widespread environmental consequences (Coffin and Eldholm, 1994).

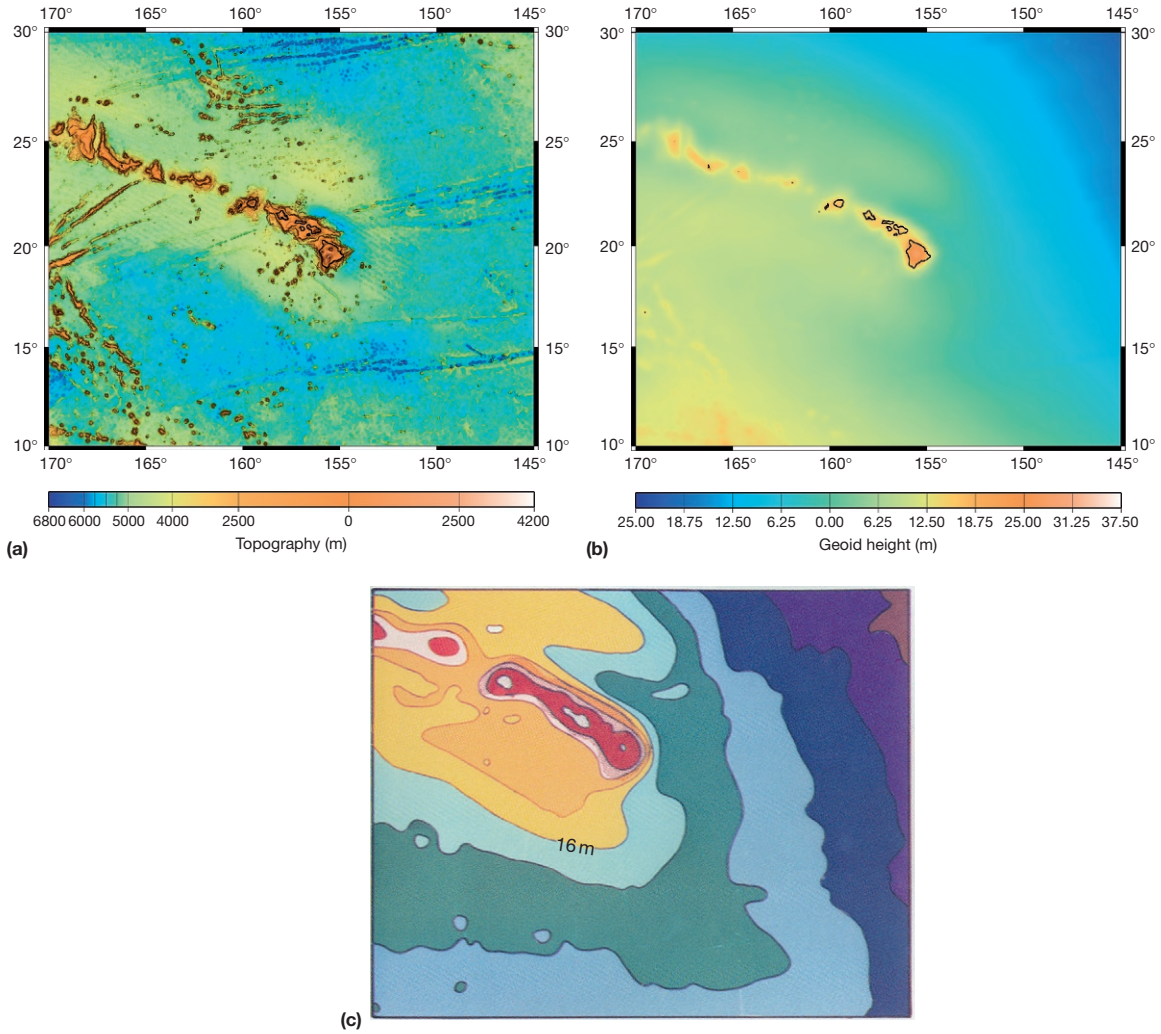

Figure 5 Regional topography (a) and geoid (b) centered on the Hawaiian Islands with the islands outlined. Note that the geoid, the equipotential surface approximating the sea surface, is smoother and lower amplitude than the topography. (c) The tear-drop shape of the Hawaiian swell at the southeast end of the Hawaiian chain is most apparent in the planform of the geoid anomaly after correcting for the geoid effect of the volcanoes and their isostatic compensation. Reproduced from McNutt MK and Shure L (1986) Estimating the compensation depth of the Hawaiian swell with linear filters. *Journal of Geophysical Research* 91: 13915–13923.

The continental examples are relatively better studied than the oceanic LIPS on account of greater accessibility on land to field geologists for mapping, sampling, and dating. Sampling of submarine LIPs is hampered by their low relief, lack of subaerial exposure except in unusual cases (e.g., Heard Island on Kerguelen), and high rate of carbonate sedimentation. Therefore, much of the inference that the massive submarine plateaus formed very quickly is based on analogy with the continental examples, such as Deccan and Siberia.

Oceanic LIPs are found in both mid-plate and plate boundary settings, although significantly they tend to lie in extensional settings (e.g., in the wake of rifting continents). They rise 2 km or more above the surrounding seafloor and display anomalously thick oceanic crust. Few data are available for testing the models for the evolution of LIPs. What little data do exist from limited drilling suggest that LIPS subside at the same rate (i.e., as the square root of age) as normal oceanic lithosphere (Coffin, 1992).

The sheer size of LIPs limits what information can be obtained on crustal structure from seismology. Even the largest airgun arrays have insufficient power to image Moho continuously across oceanic plateaus. The best information to date comes from seismic refraction experiments (e.g., Patriat et al., 2002), which show velocity increasing from 5.5 km s^{-1} in the upper crust to values between 7.0 and 7.6 km s^{-1} in the lower crust (Furumoto et al., 1976; Mutter and Zehnder, 1988).

Some laboratory and numerical experiments designed to simulate the rise of plumes through a mantle with temperature-dependent viscosity show that the leading edge of the incipient plume is a mushroom-shaped head followed by a long, thin tail (Christensen, 1984; Whitehead and Luther, 1975). Such pictures (**Figure 8**) inspired an interpretation of LIPs as the first very outpourings of basalt as the 'plume head' reaches Earth's surface, and a linear hot-spot chain as the subsequent trace of the plate's motion over the 'plume tail' (Richards et al., 1989).

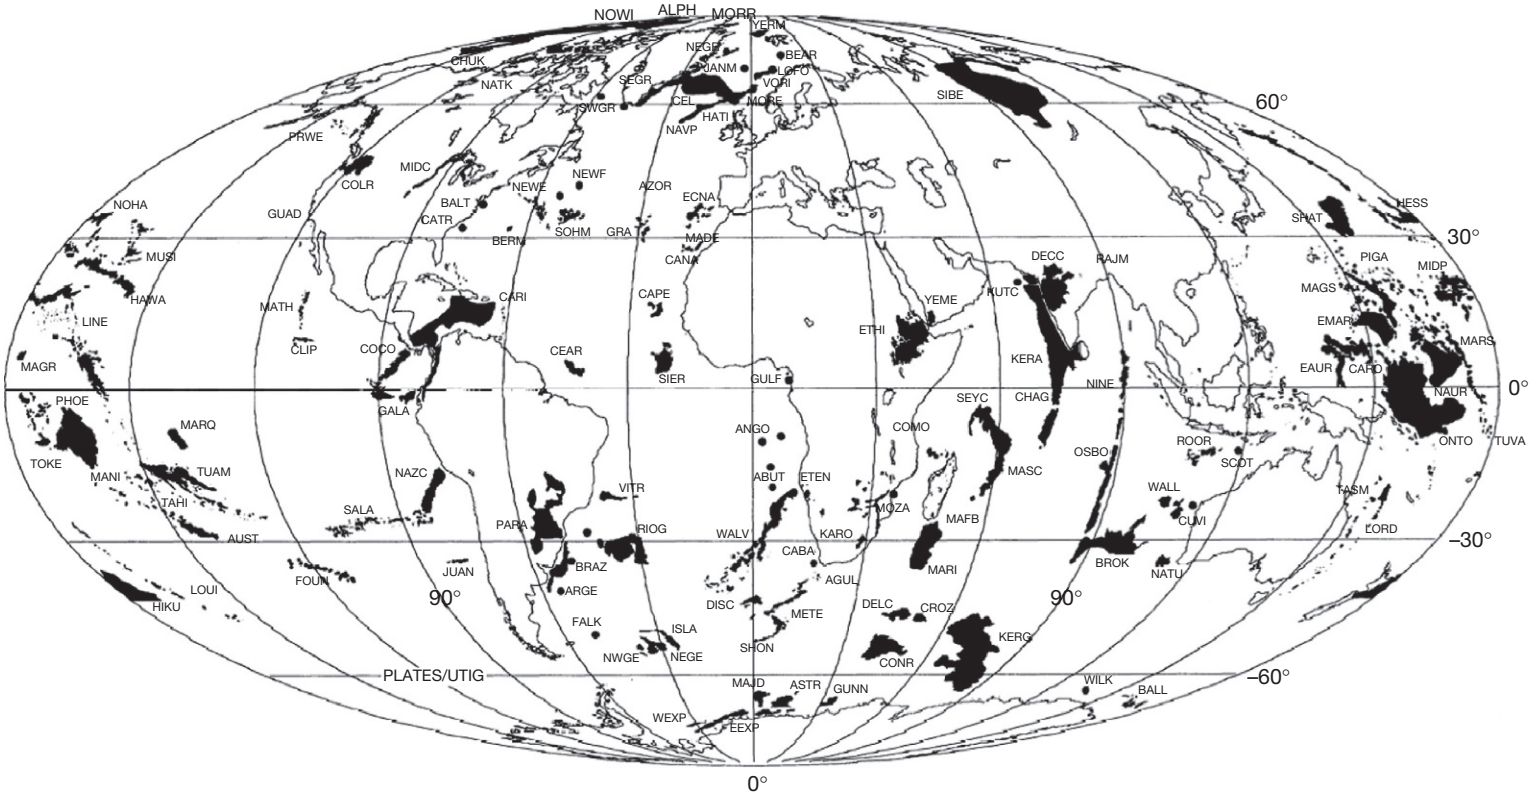

Figure 6 Global map of large igneous provinces (LIPS), including continental and oceanic flood basalt provinces, volcanic passive margins, oceanic plateaus, submarine ridges, and seamount groups. Reproduced from Coffin MF and Eldholm O (1994) Large igneous provinces: Crustal structure, dimensions, and external consequences. *Reviews of Geophysics* 32: 1–36.

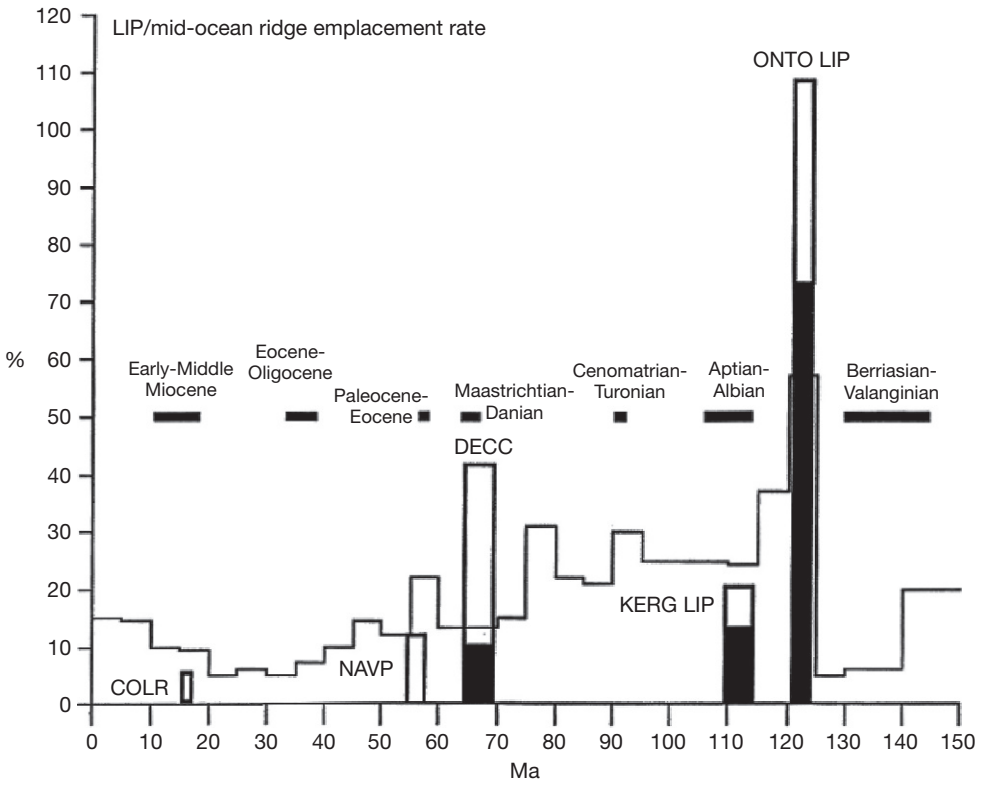

Figure 7 The volume of LIPS plotted as a percentage of the production of oceanic crust at mid-ocean ridges as a function of time. The thin line is the estimate from Larson (1991). The thick lines are estimates for the Colombia River basalts (COLR), the North Atlantic Volcanic Province (NAVP), the Deccan Traps (DECC), Kerguelen (KERG LIP, which includes Elan Bank and Broken Ridge), and Ontong Java (ONTO LIP, which includes Manihiki Plateau and the Mariana, Nauru, and Pigafetta basin flood basalts). Solid and open portions of columns indicate bounds on emplacement rates depending on assumptions concerning plate setting – on-ridge versus off-ridge, and duration of volcanism. Reproduced from Coffin MF and Eldholm O (1994) Large igneous provinces: Crustal structure, dimensions, and external consequences. *Reviews of Geophysics* 32: 1–36.

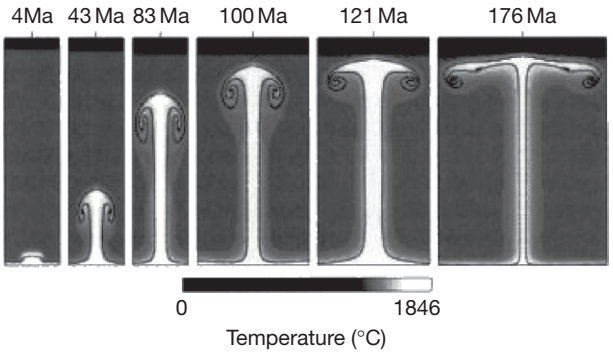

Figure 8 Sequence from a numerical model in which an axisymmetric plume grows from a thermal boundary layer in a fluid with temperature-dependent viscosity. The black line delineates fluid initially within the thermal boundary layer. Ambient viscosity is 10^{22} Pa s, the bottom boundary temperature is 430 °C above the interior temperature, and its fluid viscosity is 1% that of the interior. Reproduced from Davies GF (1999) *Dynamic Earth*: *Plates*, *Plumes*, *and Mantle Convection*, 458 pp. Cambridge: Cambridge University Press.

The agreement between the observations in the real world and the predictions from these simulations is far from perfect, however. Of 49 hot spots examined by Courtillot et al. (2003), only five definitely traced back to a LIP, with another eight to ten potentially connected to an older flood-basalt event. In a few cases, the originating LIP might have already been subducted (e.g., a Hawaiian LIP might be already recycled into the mantle in the northwest Pacific beyond the Emperor Seamounts). Nevertheless, 60% of the hot spots in their catalog were demonstrably not associated with a LIP, meaning that those hot spots are either caused by headless plumes or not caused by plumes at all. At the same time, not all known LIPs have spawned hot-spot chains from a 'plume tail.' There appears to be some nonrandom connection between LIPs and chains of hot-spot volcanoes, but too rare to support the plume head/plume tail hypothesis as a general rule. An alternate theory for the formation of LIPs, especially those on the edges of continents, is that they represent short-lived small-scale convection driven as an edge effect at strong geothermal gradients (Mutter et al., 1988). Regardless of the origin of LIPs, if the basaltic rocks represent a 5–30% partial melt extracted from the mantle, the source for melts for the largest LIPs extends through all of the upper mantle down to the transition zone and perhaps below (Griffiths and Campbell, 1991).

1.14.2.2 Aseismic Ridges

Aseismic ridges are less voluminous volcanic outpourings that otherwise have much in common with LIPs. Like the more

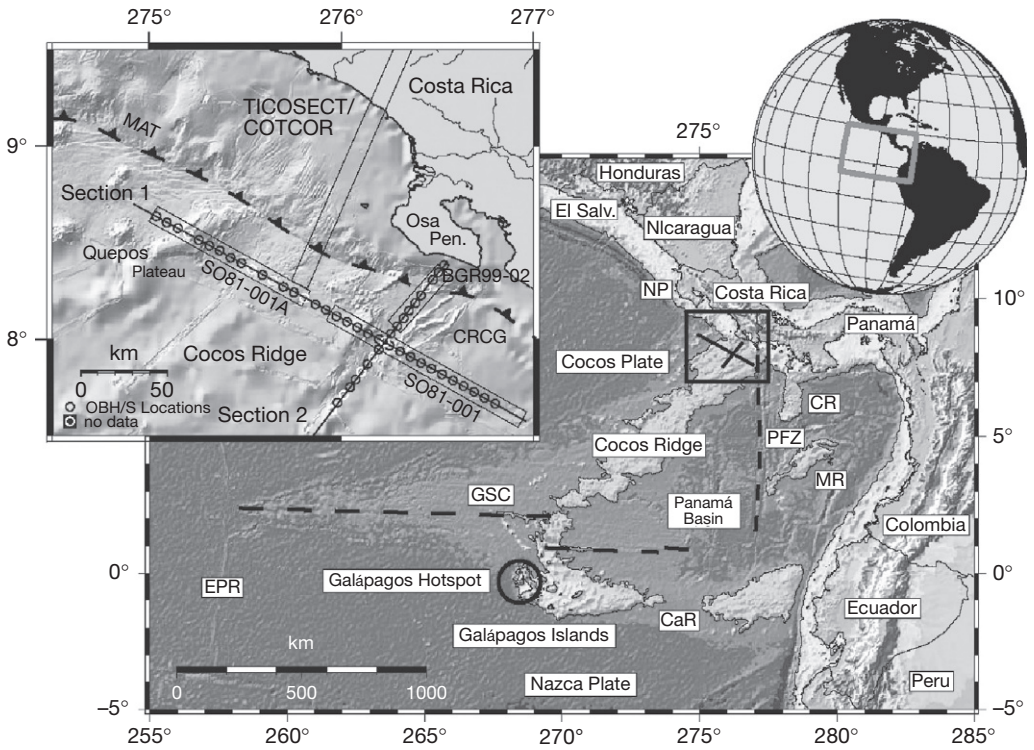

Figure 9 Location of wide-angle seismic survey undertaken by Geomar across the Cocos Ridge. The interpreted crustal structure along section 1 is shown in **Figure 10**. Reproduced from Walther CHE (2003) The crustal structure of the Cocos Ridge off Costa Rica. *Journal of Geophysical Research* 108. http://dx.doi.org/10.1029/2001JB000888.

expansive LIPs, these ridges stand 2–3 km above the surrounding seafloor and were originally termed 'aseismic' because the lack of earthquakes distinguished them from mid-ocean ridges and transform fault scarps (Laughton et al., 1970). Examples include the Cocos Ridge (**Figure 9**), Nazca Ridge, Ninetyeast Ridge, the Rio Grande Rise, the Walvis Ridge, the Chagos-Laccadive Ridge, and the Iceland-Faeroe Ridge. The occurrence of aseismic ridges in extensional settings is even more clear-cut than is the case for LIPs. The ages of the volcanic rocks are similar to that of the underlying seafloor, and their rate of subsidence parallels that of the seafloor of the same age, although offset by the excess elevation of the ridge (Detrick et al., 1977). Analysis of gravity/bathymetry ratios shows that they are locally compensated, meaning that the underlying plate had no elastic strength at the time that the ridges formed (Detrick and Watts, 1979). As is the case for LIPs, aseimic ridges do not tend to be associated with any noticeable swells.

All of this evidence supports the interpretation that aseismic ridges form when a hot spot coincides with a spreading ridge, a situation that apparently happens quite often. The excess melting from the hot spot combines with the normal crustal accretion process to form ocean crust 2–3 times thicker than would normally be the case (Ito et al., 1996, 1997; Ribe, 1995). The motion of the spreading plate away from the point of intersection of the ridge and hot spot is marked by more or less continuous ridges of thickened crust on both sides of the spreading ridge that mark the former location of excess crustal generation.

These ridges are generally age progressive, but do not always form distinct volcanoes presumably on account of the ease with which magma can rise through very young lithosphere without having to take advantage of existing magma conduits. A prediction of this theory for the origin of aseismic ridges is that hot spots that are truly centered beneath the ridge crests should create pairs of aseismic ridges on each side of the spreading center, although with different azimuths depending on the motion of each plate with respect to the locus of the hot-spot melting anomaly. This prediction is borne out in many cases; for example, the Walvis Ridge and the Rio Grande Rise form a conjugate pair across the southern Mid-Atlantic Ridge while the Cocos Ridge and the Nazca Ridge are conjugate across the Galapagos Spreading Center. If the hot spot is located close to the ridge but under only one of the plates, the morphology of the volcanoes might still resemble an aseismic ridge as the volcanism occurs on very young lithosphere, but the conjugate ridge will not form.

The results from a wide-angle seismic reflection survey (Walther, 2003) to image the crustal structure of the Cocos Ridge offshore Costa Rica in the eastern Pacific (**Figure 9**) seem typical of the results from other aseismic ridges, such as the Faroes Ridge which lies on the European Plate east of Iceland (Smallwood et al., 1999). The Moho (a seismic discontinuity representing the boundary between Earth's crust and mantle) is seen to deepen 10 km to compensate the 2 km elevation of the ridge above the surrounding seafloor (**Figure 10**). The seismic traveltimes and gravity data are best fit if the upper mantle

beneath the ridge is assumed to have a low seismic velocity and low density contrast with respect to the lower crust. What is unexpected in the Cocos survey is the amount which lower crustal thickening, as opposed to extrusive volcanism, contributes to the volume of the ridge. In the center, units with lower crustal velocity and density make up 80% of the total crustal section, and the lower crust is three times the thickness of normal oceanic lower crust. Exceptionally high velocities ($>7.4\ km\ s^{-1}$) are not seen in the lower crust, as has often been reported beneath mid-plate island chains, and the upper mantle is slower beneath the Cocos Ridge ($7.6\ km\ s^{-1}$) than the average for normal oceanic upper mantle ($\sim 8\ km\ s^{-1}$).

1.14.2.3 Superswells

Superswells (Figure 11) represent clusters of hot spots in a restricted geographical region of anomalously high elevation

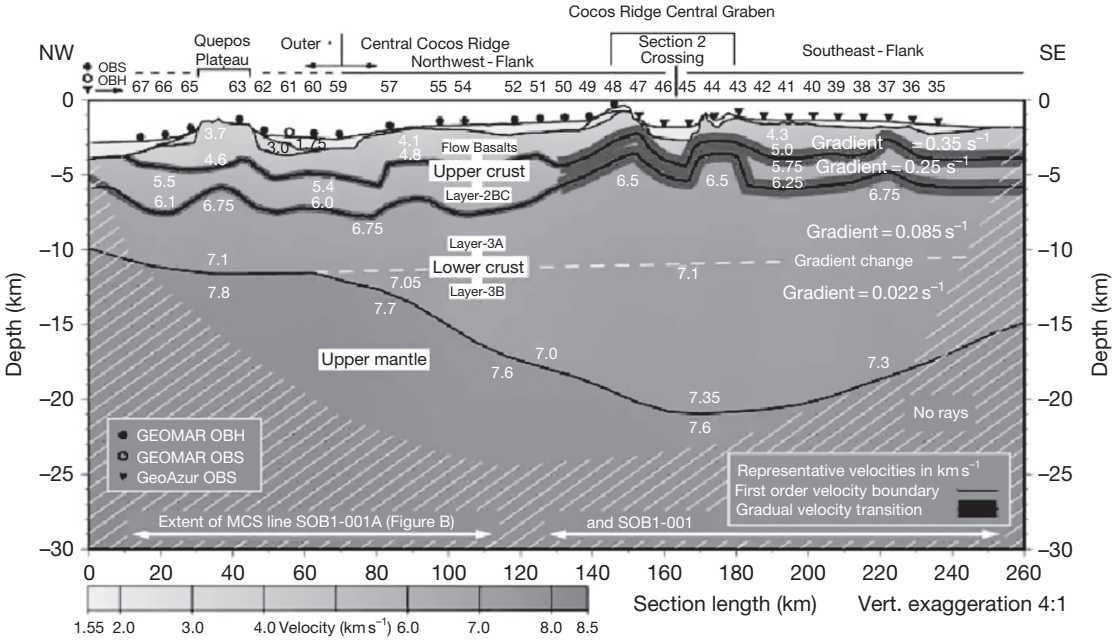

Figure 10 Crustal model for a 260-km-long transect across the Cocos Ridge, 35 km seaward of and parallel to the middle America Trench (location shown as section 1 in Figure 9). Velocities are displayed in gray scale and for representative values in kilometers per second. The hatched area is not resolved. The crustal thickening of the Cocos Ridge occurs primarily within the lower crust rather than the surficial extrusives. There is no evidence for unusually high lower crustal velocities, and indeed the upper-mantle velocities are unusually low. Reproduced from Walther CHE (2003) The crustal structure of the Cocos Ridge off Costa Rica. *Journal of Geophysical Research* 108. http://dx.doi.org/10.1029/2001JB000888.

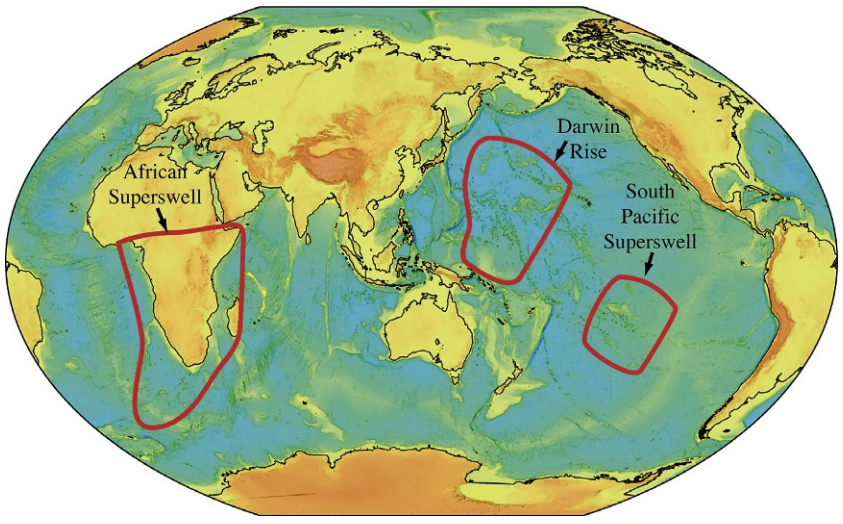

Figure 11 The African (Nyblade and Robinson, 1994) and South Pacific (McNutt and Fischer, 1987 and McNutt and Judge, 1990) superswells are regions exhibiting anomalously shallow topography and unusually copious recent volcanism. The Darwin Rise has been interpreted as the location of a Cretaceous superswell (McNutt et al., 1990).

that cannot be explained by crustal thickening. The first area so recognized was in the South Pacific (McNutt and Fischer, 1987). Volcanoes higher than 200 m are ten times more likely to be found on the seafloor of the South Pacific superswell as compared to regions elsewhere in the Pacific even apart from the hot-spot chains (Bemis and Smith, 1993), suggesting that mid-plate volcanism at all scales is enhanced. Much of the seafloor now in the northwest Pacific appears to have been a superswell during the Cretaceous (McNutt et al., 1990). The African superswell (Nyblade and Robinson, 1994) is a continental example of the same phenomena – unusual clusters of hot spots on a topographically elevated region. Individual hot-spot volcanoes located within superswells do tend to have their own swells, but they are small and only rise above the background depth anomaly of the superswell when located on very old lithosphere (McNutt, 1998; Sichoix et al., 1998).

Some of the Pacific hot-spot island chains that diverge the most from the predictions of plume theory are found on the superswell, and in fact superswell-type lithosphere appears to be very 'leaky' in terms of facilitating the ascent of magma to the surface (McNutt, 1998). Larson (1991) proposed that superswells are produced by superplumes, which can be envisioned as long-lived by very broad upwelling in the mantle. The fact that superswells are so large makes them a relatively easy target for using reconnaissance geophysical data, particularly tomographic mantle seismic structure, to search for evidence of Larson's proposed superplume or any other features in the mantle that might contribute to the unusual amount and distribution of volcanism. Nishimura and Forsyth (1985) were the first to note low seismic velocities in the upper mantle beneath the South Pacific superswell using an analysis of Love-wave phase velocities. Global inversions performed since then (e.g., **Figure 12**) confirm the slow velocities in the upper mantle and extend them to the lower mantle beneath both the South Pacific and the African superswells (Dziewonski, 2005; Dziewonski and Woodhouse, 1987; Grand et al., 1997; Masters et al., 1996; Su et al., 1994), although they differ in the details of how continuous the anomalous velocity structure is across the transition zone.

1.14.2.4 Mid-Plate Volcanic Chains and Clusters

Hot spots that do not fall into any of the categories above form isolated mid-plate volcanic chains and clusters (**Figure 13**). This is the most classic form of hot-spot volcanism, and examples in this category show the most prominent hot-spot swells. Examples include the Hawaiian (Clague and Dalrymple, 1987) and Louisville (Lonsdale, 1988) chains on the Pacific Plate (**Figure 13**), the Easter Island chain (O'Connor et al., 1995) on the Nazca Plate (**Figure 13**), Bermuda (Detrick et al., 1986) on the North American Plate, Cape Verde (Ali et al., 2003; Courtney and White, 1986), the Canary Islands (Watts et al., 1997), and Reunion (Charvis et al., 1999; Gallart et al., 1999) on the African Plate, and many other young island and seamount groups found on mature lithosphere. Because plates and plate boundaries are always drifting relative to the locus of hot-spot volcanism, it is not unusual for a mid-plate hot spot that is forming a chain of individual volcanoes to drift close enough to a ridge crest, and then begin to form an aseismic ridge or conjugate pair of ridges. Hot spots can move away from ridges as well. Precise dating is key to understanding what portions of hot-spot volcanism has been influenced by proximity to a ridge.

Most of the geophysical investigation of hot spots using seismic and other methods has focused on this category of hot spots, and their close relatives on superswell-type lithosphere, because the anomalous characteristics that must be explained are more easily identified. For example, beyond their unusually thick crust, there is little in terms of a geophysical anomaly associated with aseismic ridges that might

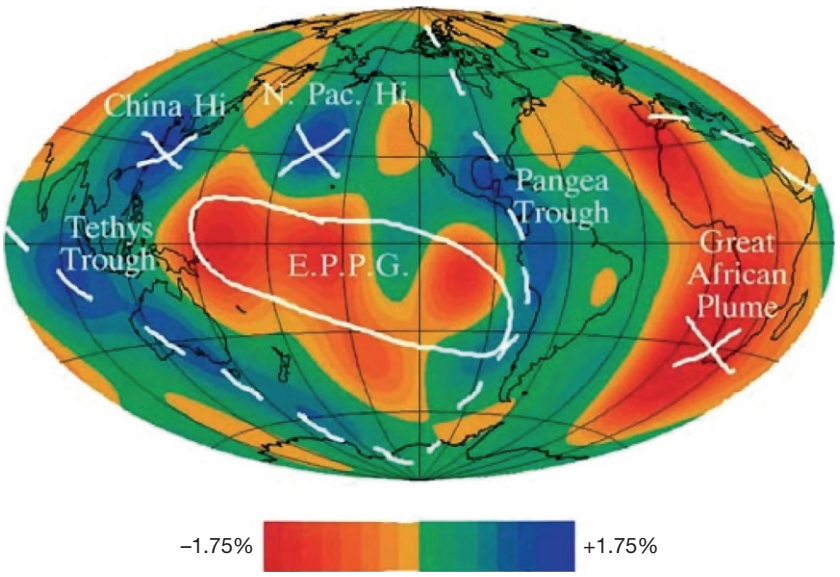

Figure 12 Global seismic tomographic image of shear-wave velocities at 2750 km depth. The South Pacific superswell (here labeled E.P.P.G. for Equatorial Pacific Plume Group) and the African superplume (here labeled Great African Plume) regions are associated with deep low-velocity anomalies that extend upward toward the surface. Reproduced from Dziewonski AM (2005) The robust aspects of global seismic tomography. *Geological Society of America Special Paper* 388: 147–154.

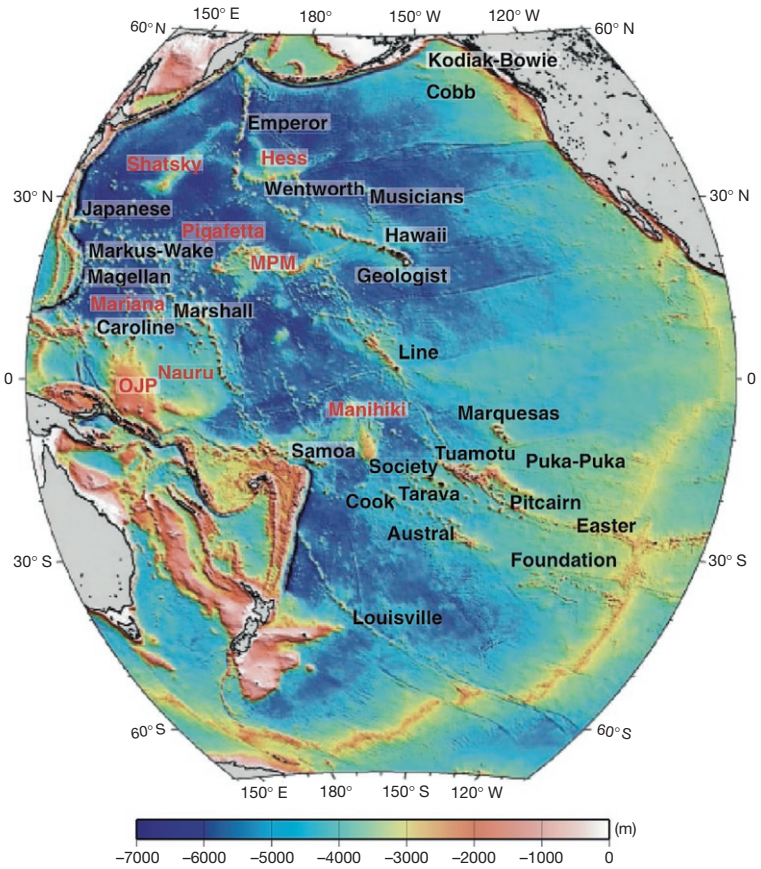

Figure 13 Linear volcanic chains shown on a bathymetric map of the Pacific Plate. Seamount chains are named in black; oceanic plateaus are named in red. MPM, Mid-Pacific Mountains; OJP, Ontong Java Plateau. Most seamounts occur in linear chains or clusters. Reproduced from Clouard V and Bonneville A (2005) Ages of seamounts, islands and plateaus on the Pacific Plate. In: Foulger GR, Natland JH, Presnall D, and Anderson DL (eds.) *Geological Society of America Special Paper 388: Plates, Plumes & Paradigms*, pp. 71–90. Boulder, CO: Geological Society of America.

provide clues to the cause of the excess melting. LIPs are clearly more extreme events, but their sheer size confounds a clear separation of spatial and temporal events to probe causative mechanisms.

1.14.3 Geophysical Characteristics of Hot Spots

Basic geophysical observations such as depth, subsidence, gravity and geoid anomalies, and heat flow can be used to probe the crust and lithospheric structure of hot spots and their swells. In fact, seismic investigations proceed usually only after all other data types have been exhaustively analyzed, as seismic field programs tend to be the most expensive to undertake. Briefly, we review the geophysical characteristics of hot spots and what they imply for crustal and lithospheric structure.

1.14.3.1 Orientation and Age

Hot spots erupting on the Pacific Plate (both as classic mid-plate volcanism and superswell-type volcanism) tend to form linear chains of volcanoes, with the Hawaiian–Emperor chain forming one of the longest on the planet. Early on, this chain was shown to have a monotonic age progression to the west-northwest (Clague and Dalrymple, 1987). The trend of the chain and its age progression define the pole and rate of rotation for the Pacific Plate relative to the Hawaiian hot spot, and changes in the position of the pole and its drift rate through time. If the source of the hot spot is a stationary mantle plume, as proposed by Morgan (1971), then the rotation so derived should be the absolute motion of the Pacific Plate. This hypothesis that plumes might form a fixed reference frame against which the direction and rate of plate drift could be measured has now been shown to be incorrect. Tarduno et al. (2003) used paleomagnetic data from seamounts along the Emperor part of the Hawaiian–Emperor chain to test whether the paleolatitude of the Hawaiian hot spot had remained fixed over time. They concluded that the source of the Hawaiian melting anomaly moved at velocities exceeding 40 mm per year, a rate similar to the rate of plate drift, during the Late Cretaceous and Early Tertiary.

Even though the notion of mantle plumes firmly anchored at the CMB must be abandoned, the orientations of most other active hot-spot chains on the Pacific Plate are co-polar with the Hawaiian chain, with the exception being the Marquesas (Crough and Jarrard, 1981). Furthermore, most chains of guyots and seamounts with Late Cretaceous and Early Tertiary

ages are parallel to the Emperor part of the Hawaiian chain. These trends support the theory that hot spots form from plumes that are at least fixed with respect to each other, except for the fact that Kr–Ar and Ar–Ar dating demonstrated that only a few other Pacific volcanic chains, such as the Society Islands and possibly the Louisville seamount chain, show the predicted age progression (Duncan and McDougall, 1976; Koppers et al., 2004; Lonsdale, 1988). The age discrepancies are equally apparent for older seamount chains, such as the Line Islands, which are co-polar with the Emperor seamounts, but lack a simple age progression (Schlanger et al., 1984). At first, geophysicists and geochronologists attempted to explain the errant age distributions as the superposition of effects from several plumes that line up along the same trend, but the numbers of required plumes are ultimately untenable (McNutt et al., 1997).

For the large number of linear chains that do not show monotonic age progressions, the most common age pattern is nearly synchronous volcanism at several volcanic centers along the chain, with short age progressions in the Hawaiian sense. Perhaps significantly, none of the linear chains on the Pacific Plate show age progressions in the direction counter to the Hawaiian direction of progression. Therefore, while the plume model in detail is not a good fit to the majority of hot spots, the sequence of hot-spot eruptions is not completely random in space or time. Another explanation that has been proposed is that hot spots result from the rise of magma from more ubiquitous melt bodies in the upper mantle along lithospheric cracks (Anderson, 1996; Bonatti and Harrison, 1976; Davis et al., 2002; Turcotte and Oxburgh, 1973), with the parallel trends resulting from a consistent plate-wide stress field. However, none of the Pacific chains display ages converging toward a central initiation point, as might be the case for volcanism occurring along a tensional tear in the plate.

In the Atlantic, the major island groups in this category do not form obvious lines, presumably because the hot spot is close to the Euler pole of rotation for the Atlantic Plate with respect to the melting anomaly (e.g., Cape Verde Rise; Morgan, 1971). For this reason, Pacific hot spots have received most of the attention in terms of using orientations and ages to test the plume hypothesis.

1.14.3.2 Depth and Subsidence

The height of the mid-plate swell surrounding the region of active volcanism also provides clues to the origin of hot spots. Crough (1978) noted that ten hot-spot swells in the Pacific, Atlantic, and Indian Oceans all rise to depths of about 4000–4500 m, regardless of crustal age. Therefore, the depth anomaly (with respect to either some standard model or to the surrounding seafloor) for these swells increases with the age of the oceanic lithosphere at the time that the volcanoes erupted. There also appears to be some positive correlation between the size of the Hawaiian swell and the volume of the volcanoes through time (Phipps Morgan et al., 1995), although it is difficult to correlate these two quantities back very far in time because there is no discernible swell along the Hawaiian/Emperor chain that is more than 43 My in age (Vidal and Bonneville, 2004).

Abyssal hills created at a mid-ocean ridge outcrop on the swell away from the volcanoes and their sedimentary debris aprons ('archipelagic aprons,' Menard, 1956), indicating that the seafloor has been lifted up from below. The source of the uplift must be a reduction in density of the rocks somewhere beneath the swell, as geoid data (reviewed below) indicate that swells are isostatically compensated. The source of the density reduction could be heat, or a modification in either rock mineralogy or chemistry that reduces its density. Furthermore, the location of the buoyant material could be within the crust (e.g., by thickening the crust from below), lithosphere (e.g., by reheating the lithosphere by the hot spot), or asthenosphere (e.g., by upward flow of a hot plume). In order to narrow down the possibilities, other information such as subsidence rates, geoid anomalies, heat flow, and seismic data have been interpreted along with depth anomalies. For example, to first order, as the depth to the compensating mass increases, so does the height of the geoid anomaly over the swell. Seismic velocity is slower for rocks that have low density because they are hot, but faster for rocks that have low density by virtue of extraction of a basaltic melt component.

The fact that swells are larger on older lithosphere has been used to support a thermal explanation for the swell, because thermal contrasts from hot-spot source materials would be larger in comparison to old, cold, mature lithosphere than young lithosphere. The observed correlation between swell volume and volume of the volcanoes has been used to argue for a chemical origin for swells, as the volume of buoyant, residual mantle remaining after the extraction of the basaltic melt component should scale with the amount of melt removed.

The chemical swell origin hypothesis has been contradicted by several studies that concluded swells subside faster than normal oceanic lithosphere of the same age. Some of the clearest evidence for this anomalous subsidence has come from volcanoes in the western Pacific that formed on a former superswell (McNutt et al., 1990). Seismic reflection data image the contact between the reef and pelagic sediments capping former hot-spot islands that have now subsided to create guyots (Winterer et al., 1993). The height above the seafloor of the basement contact measures the depth of the seafloor soon after the volcano erupted, on the very reasonable assumption that wave action bevels the volcano to sea level within a few million years. In the western Pacific, this depth is less than normal for lithosphere of that age, providing an estimate of the height of the superswell at the time of Cretaceous volcanism. The depth below sea level of that contact measures how much the seafloor has subsided to the present. Data from both the seismic reflection surveys and from drilling atolls (e.g., Ladd and Schlanger, 1960; Ladd et al., 1967) indicate accelerated subsidence, favoring some sort of heat anomaly in the upper mantle that decays with time.

To explain the subsidence, Detrick and Crough (1978) introduced the concept of lithospheric thinning. According to this hypothesis, heat from a hot spot resets the temperature of the lower lithosphere below some depth (typically 40–50 km) to the temperature of the underlying asthenosphere. They showed that the anomalously high rate of observed subsidence was appropriate for lithosphere of that depth, as though the lithosphere had been reheated by the hot spot to a more

youthful thermal structure. They argued that the tear-drop shape of the Hawaiian swell and its rate of subsequent subsidence along a conductive cooling curve were unlikely to be produced by a lithospheric plate drifting over a 'bump' in the asthenosphere (Menard, 1973) dynamically maintained by an upwelling mantle plume. They noted that the difficulty with their lithospheric thinning hypothesis was the requirement for exceptionally high rates of heat flux into the base of the lithosphere given the observation that it only takes ~3 My for the Hawaiian seafloor to rise from normal depths to the peak of the swell.

1.14.3.3 Geoid Height

The fact that swells were observed to subside along the predicted trajectory for a conductively cooling plate is consistent with a lithospheric origin for the depth anomaly, but the subsidence of depth anomalies only measures the change in buoyancy throughout a vertical column. The elevation information alone is insensitive to the depth of the causative source. The geoid, the gravitational equipotential surface coinciding with the mean sea surface, is smoother and varies less than elevation (no more than ±100 m globally relative to the reference ellipsoid), but reflects the depth of underlying low- or high-density anomalies. Geoid data, either as estimated from satellite radar altimeters (**Figure 5**) or as converted from gravity, have been used to estimate the depth to the low-density material supporting hot-spot swells on about 24 examples around the world (Crough, 1978; Monnereau and Cazenave, 1990, 1998). The first simplistic interpretations of geoid data used ratios of swell height to geoid height, which in an infinite wavelength approximation would yield the compensation depth of the swell (Haxby and Turcotte, 1978). More sophisticated analysis takes into account the limited frequency content of the swell and the flexural compensation of the volcanoes (**Figure 5**), but still assumes simple dipole-like compensation (McNutt and Shure, 1986). For mid-plate swells, the compensation depths so determined were in the mid- to lower lithosphere, and the depth to the compensation increases with the age of the lithosphere, which supports the lithospheric thinning model.

However, as pointed out by Robinson and Parsons (1988), there are mechanisms for supporting a mid-plate swell that would place all the compensating material below the lithosphere, but still have an apparent depth of compensation lie well within the lithosphere. This situation could arise, for example, if a low-density mass is rising in a viscous asthenosphere. The induced flow would warp density interfaces above the rising mass (e.g., the swell at Earth's surface) and below the mass (e.g., in the transition zone or at the CMB). The net effect is that the swell and its compensation would be better represented as a tripole, and interpretation of the data in terms of a density dipole would give an incorrectly shallow compensation depth for the swell. An additional complicating factor is the possibility that the composition of the lower lithosphere itself is altered in the process of the hot-spot extracting basaltic melt, leading to buoyant uplift of a swell (McNutt and Bonneville, 2000; Phipps Morgan et al., 1995). Without additional information on crustal and mantle structure, it is not possible to resolve the ambiguity in the interpretation of the elevation and geoid data.

1.14.3.4 Elastic Plate Thickness

Estimates of effective elastic plate thickness are also sensitive to temperature beneath mid-plate swells (McNutt, 1987). When volcanoes erupt in mid-plate settings, they are isostatically compensated by the lithosphere warping in an elastic manner beneath the weight of the volcano. Marine gravity data are very sensitive to the stiffness of the plate, with stiffer plates producing larger free-air gravity anomalies over the volcanoes and a longer distance from the flexural moat surrounding the volcano to the flanking arch. A similar elastic bending occurs where oceanic plates subduct into the mantle at deep-sea trenches. Watts et al. (1980) used shipboard gravity and bathymetry data to estimate the effective elastic thickness for mid-plate islands and trenches worldwide (**Figure 14**). They determined an empirical relationship,

$$T_c = 2.7\sqrt{t}$$

where t is the age of the lithosphere in million years and T_e is its effective elastic thickness in kilometers. Using standard thermal models for lithospheric plates (e.g., Parsons and Sclater, 1977), the base of the elastic portion of the lithosphere would correspond to the depth of the ~450 °C isotherm.

A number of hot-spot volcanoes, particularly those on the South Pacific superswell, show T_e values that require shoaling of the 450 °C isotherm (Calmant, 1987; Calmant and Cazenave, 1986; McNutt, 1984). At first, this was interpreted as strong evidence in favor of the lithospheric reheating model, as it appeared to require elevated temperatures well within the lithospheric portion of the mantle. However, McNutt et al. (1997) demonstrated in the Austral Islands that one consequence of volcanic overprinting caused by multiple volcanic centers along the same linear trajectory would be low estimates for elastic plate thickness. The earlier phases of volcanism, which loaded a younger and therefore weaker plate, are difficult to detect and date because they are covered over by the most recent volcanic activity. If the entire load is assumed to be the same age as the surface lavas, the estimated elastic thickness is some compromise between the low value for the older phase of volcanism and the higher value for the more recent phase. Given how few hot-spot chains show one simple linear age progression, particularly for superswell hot spots, underestimating the true mechanical strength of the lithosphere beneath hot spots is likely quite common.

Ideally, one would like to be able to compare elastic thickness estimates for volcanoes on hot-spot swells with those from entirely different geologic settings where no thermal processes are associated with forming the loads that flex the plate. The outer rises formed where plates bend before descending into the mantle provide the best opportunity to calibrate the elastic thickness in a setting free from any thermal disruption. The estimates of elastic thickness from trenches are similar to those determined for volcanoes on swells. The current consensus seems to be that the effective elastic thickness of the lithosphere where it is flexed over hot-spot swells is not much different from that of lithosphere unaffected by hot-spot volcanism.

1.14.3.5 Heat Flow

Heat flow observations, defined as the product of thermal conductivity k of the sediments at the surface of the plate and

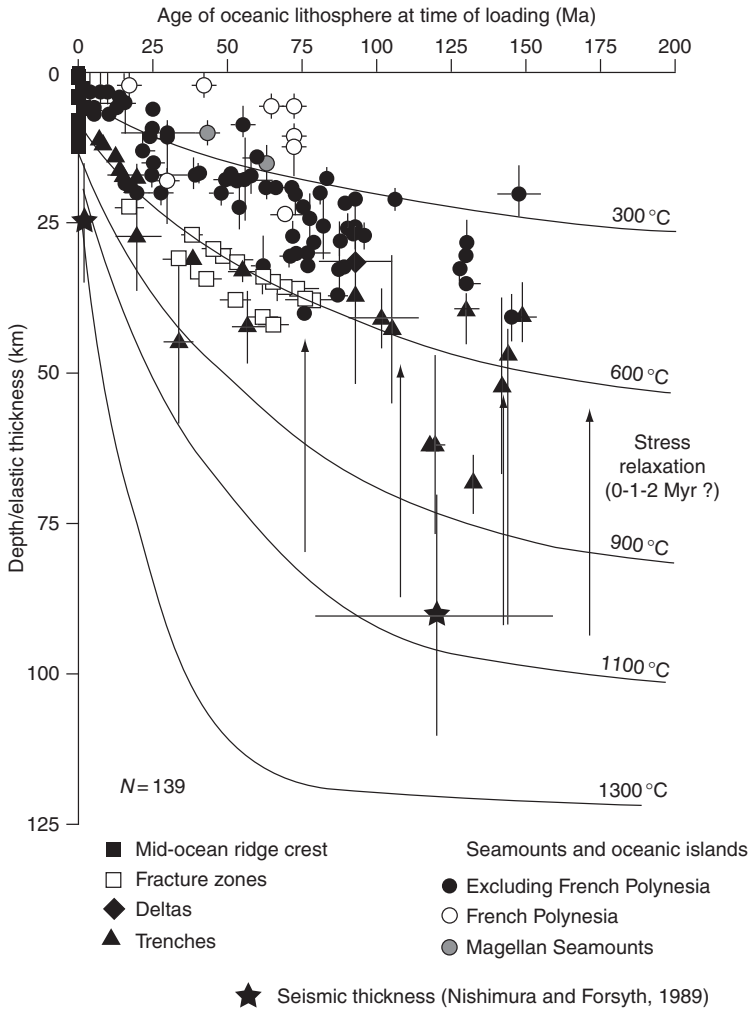

Figure 14 Plot of elastic plate thickness against the age of the lithosphere at the time of loading for oceanic lithosphere. Also shown are two measurements of lithospheric thickness from seismic surface wave studies (Nishimura and Forsyth, 1985). These data indicate that the elastic plate thickness increases as the lithosphere ages and cools, and that the thickness of the lithosphere exhibiting flexural rigidity is less than the plate thickness inferred from seismic observations. Reproduced from Watts AB (2001) *Isostacy and Flexure of the Lithosphere*, 458 pp. Cambridge: Cambridge University Press.

the temperature gradient dT/dz, also have the potential to distinguish among different models for the distribution of any heat associated with hot spots. If hot spots are not hot at all (e.g., melting caused by decompression or addition of volatiles), then one would expect no heat flow anomaly associated with hot spots. If excess heat is involved, there should be a heat flow anomaly detected at the seafloor eventually, but its appearance would be delayed by the time it takes for temperature to conduct through the lithosphere to the surface from its point of origin. Therefore, the delay time between the onset of hot-spot volcanism and the detection of a heat flow anomaly provides an estimate for the depth to the heat source.

Detrick et al. (1981) conducted a heat flow survey occupying seven sites along the Hawaiian arch just south of the islands (**Figure 15**). They found that near the active volcanoes on the island of Hawaii, heat flow is normal for 80–90 Ma lithosphere. But further along the arch, near volcanoes that are 6 My old, the heat flow values were 5–8 mW m^{-2} higher than expected, or about 10% above the baseline value (**Figure 16**). Heat flow remained elevated to at least 22 Ma down the swell. The pattern of the anomaly was consistent with the predictions of the lithospheric reheating model, and indicated that the lithosphere had been thinned to 40–50 km depth (Von Herzen et al., 1982). The survey was criticized, however, for not having sampled the heat flow values at sites in the same general part of the Pacific but well off the swell. Given the large scatter in heat flow values worldwide, was it possible that the pattern was unrelated to the Hawaiian swell?

To better constrain the pattern and amplitude of anomalous heating of the plate beneath Hawaii, Von Herzen et al. (1989) conducted a second survey across the Hawaiian swell at Maro Reef (**Figure 15**), the locus predicted to display the maximum anomalous heating if the plate is thinned to only 40 km. The line of heat flow stations was long enough such that the beginning and end of the line would be well onto normal oceanic lithosphere off the swell. Rather than reducing the uncertainties from the earlier survey, the Maro Reef survey raised more questions than it answered. The pattern of heat

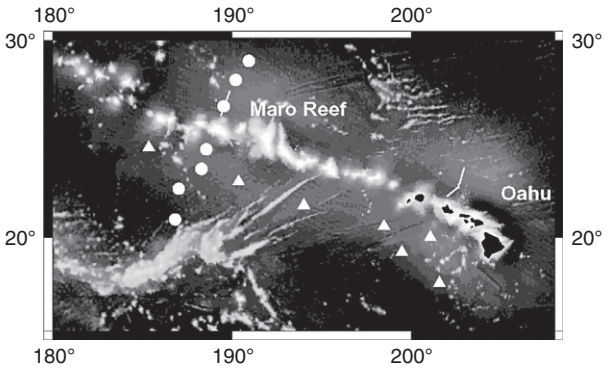

Figure 15 The Hawaiian Islands in the central Pacific and location of heat flow stations. The triangles are the South Arch survey of Detrick et al. (1981). The circles are the Maro Reef survey of Von Herzen et al. (1989). The solid white lines north of Maro Reef and Oahu show the location of dense heat flow measurements collected by Harris et al. (2000a). Reproduced from McNutt MK (2002) Heat flow variations over Hawaiian swell controlled by near-surface processes, not plume properties. In: Takahashi E, Lipman PW, Garcia MO, Naka J, and Aramaki S (eds.) *Geophysical Monograph Series*, *vol. 128: Hawaiian Volcanoes*: *Deep Underwater Perspectives*, pp. 365–372. Washington, DC: American Geophysical Union.

flow at the eight stations display a W pattern, with the highest heat flow values located near the center of the line at Maro Reef and off the swell (**Figure 16**), on supposedly normal lithosphere. Four out of the six stations sampling heat flow on the swell had resolvably lower heat flow than the sites off the swell, given the uncertainties in the data. The observations were definitely not compatible with the predictions of the lithospheric thinning model. However, with only eight stations spaced across 1200 km and each defining a local high or low in the pattern, it was impossible to conclude anything about the physical processes that might give rise to this remarkable heat flow.

Harris et al. (2000a) conducted more detailed sampling of heat flow across the Hawaiian swell at two locations, near Maro Reef (~17 My since hot-spot volcanism) and Oahu (~4 My years since hot-spot volcanism) (**Figure 15**). They found that the mean heat flow on the Hawaiian swell is slightly larger at Oahu (74.2 ± 14.6 mW m^{-2}) than at Maro Reef (64.0 ± 4.9 mW m^{-2}). No model for thermal sources below the lithosphere, unless the lithosphere were thinned to but a few kilometers thickness by a hot spot, would predict that elevated heat flow could be detected on the swell just 4 My after the onset of hot-spot activity. Harris et al. (2000b) concluded that a more likely explanation for the heat flow values over the Hawaiian swell is that the high relief of the hot-spot volcanoes is driving large-scale circulation of seawater through the permeable oceanic basement rocks underlying a more impermeable sediment blanket. This hydrothermal system mines heat from within the volcano itself, and discharges it through isolated basement highs that penetrate the sediment blanket. According to this model, younger regions of the swell, such as near Oahu, would show greater variability in heat flow because the sediment capping is less developed than further along the swell at Maro Reef. Heat flow values over the flexural moat would be the lowest on account of the large amount of volcaniclastic sediment infill, with higher values near the volcanic edifice and beyond the flexural arch. These observations are in good agreement with the data from the Hawaiian surveys and from a similar survey conducted at the Réunion hot spot (Bonneville et al., 1997).

McNutt (2002) supported this interpretation of the heat flow data by noting that the W pattern of the heat flow over the Hawaiian swell at Maro Reef is actually produced by a W pattern in the large measured variations in thermal conductivity of surface sediments (**Figure 16**). The temperature gradients themselves show an M pattern and do not dominate the resulting heat flow. Temperature gradients and thermal conductivity are also inversely correlated along the original south arch survey at Hawaii (**Figure 16**). The data indicate that areas of high conductivity act as radiators while areas of low conductivity act as insulators, producing nonuniform conduction of heat to the seafloor that is controlled by variations in surficial thermal conductivity. The simplest model that reproduces quantitatively the observed correlations between heat flow, temperature gradient, and thermal conductivity assumes two conducting layers above an isothermal layer at depth (**Figure 17**). Surprisingly, the best fit of the model parameters to the data, assuming that the upper layer corresponds to the pervasive blanket of pelagic sediments into which the heat flow probe is inserted, yields a total temperature drop from the ocean to the isothermal layer of only 21 °C, and a depth to the base of the lower conducting layer of only 500–900 m. The isothermal layer, therefore, resides within the upper oceanic crust, where pervasive fluid circulation homogenizes any lateral variations in temperature that might be associated with the Hawaiian hot spot. McNutt (2002) thus concluded that variations in heat flow across the Hawaiian swell are controlled by variability in the thermal conductivity of surface sediments, reflecting geological factors such as carbonate content.

These recent studies have underscored the importance of seismic reflection images in site selection and in the interpretation of marine heat flow. Prior to the recognition of fluid flow in the upper crust surrounding hot spots, the only concern was to avoid hard rock outcrops that would bend the heat flow probe or at least prevent a successful vertical insertion into more pliable sediments. After the realization that more permeable rock outcrops significantly perturb the hydrologic regime by serving as foci for venting and recharge of crustal fluids, avoiding any basement relief in choosing heat flow sampling sites became even more essential. Interpretation of heat flow data in terms of conductive transfer of heat from subcrustal levels to the ocean through a uniform and impermeable sedimentary blanket cannot be attempted unless there is the seismic coverage to rule out basalt outcrops penetrating the sediments. For these applications, single-channel seismic data will often suffice, but multichannel data to image faults in the basement and overlying sediments are even better.

Heat flow has been sampled over other swells, such as Cape Verde (Courtney and White, 1986) and Bermuda (Detrick et al., 1986). Both swells show a modest rise in heat flow (10–20%) near the peak of the swell as compared with values on the nearby abyssal plains, supporting the hypothesis that hot spots are hot. The results from these Atlantic swells, however, are not very useful for determining the depth to the hot material, because the volcanism is concentrated in one area

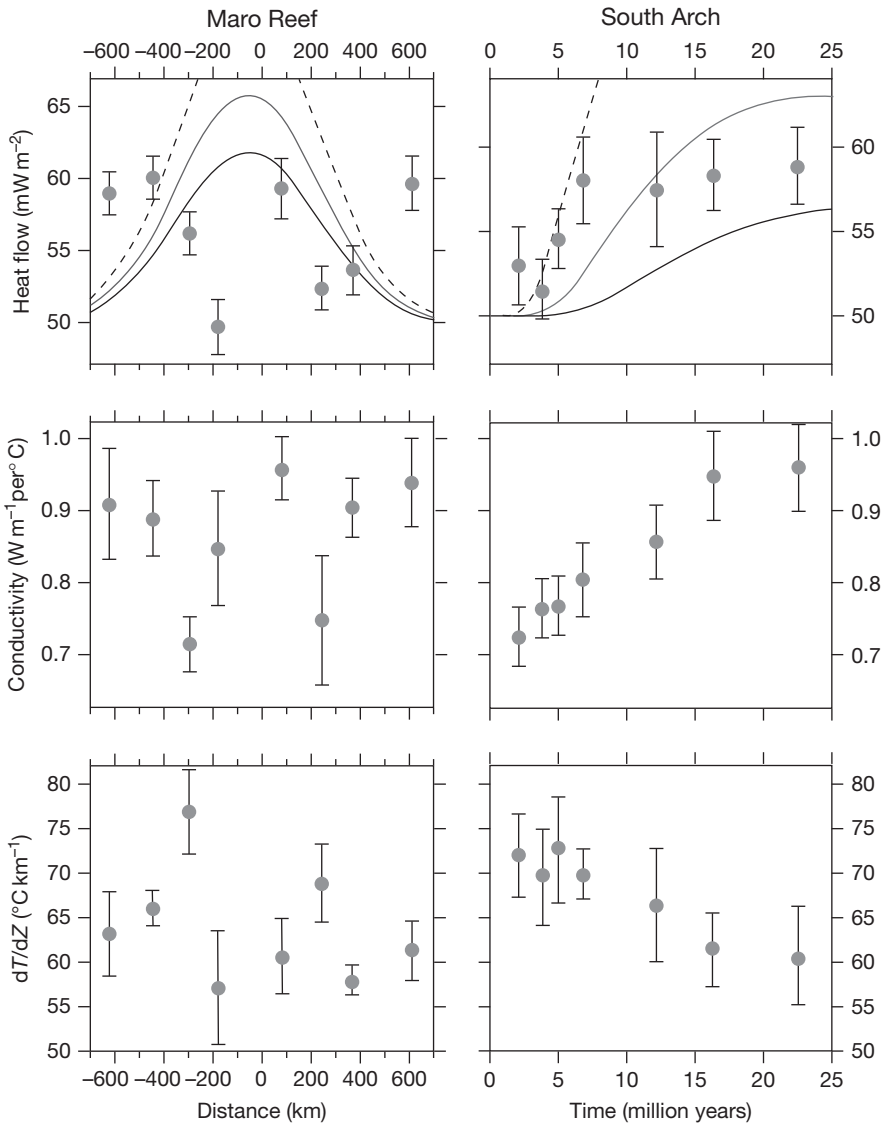

Figure 16 Left: Heat flow (upper), conductivity (middle), and vertical temperature gradient (lower) at Maro Reef (Von Herzen et al., 1989) plotted as a function of distance across the chain. Right: Heat flow (upper), conductivity (middle), and vertical temperature gradient (lower) along the south arch of the Hawaiian Islands (Detrick et al., 1981) plotted as a function of time since the plate drifted past the hot spot. Lines on the upper panels show the theoretical variations in heat flow expected if the hot spot reheated the lower lithosphere to asthenospheric values (~1350 °C) as it passed over the thermal source. The amount of thinning assumed is 60 km (solid line), 50 km (dotted line), and 40 km (dashed line). Reproduced from McNutt MK (2002) Heat flow variations over Hawaiian swell controlled by near-surface processes, not plume properties. In: Takahashi E, Lipman PW, Garcia MO, Naka J, and Aramaki S (eds.) *Geophysical Monograph Series, vol. 128: Hawaiian Volcanoes: Deep Underwater Perspectives*, pp. 365–372. Washington, DC: American Geophysical Union.

(just one Miocene volcano in the case of Bermuda), making it impossible to estimate how long it took for the heat flow anomaly to be manifest at Earth's surface.

It has been known for years that heat flow on young (<65 Ma) lithosphere is significantly perturbed and biased by hydrothermal circulation (Lister, 1972). In his recent review of marine heat flow observations worldwide, Von Herzen (2004) concluded that at least 40% of all heat flow observations on seafloor 65–95 Ma show evidence for hydrothermal circulation, and the fraction only drops to 30% for even older lithosphere. He suggested, however, that the circulation in mature lithosphere (>60 Ma) might be merely redistributing heat within a permeable basement beneath sediments without advective gain or loss, which would then lead to conductive heat flow variations controlled by thermal conductivity as advocated by McNutt (2002). Therefore, the heat flow mean as determined from many measurements over a large area should represent the true heat flux through the lithosphere. On this assumption, one can conclude that there are modest (10–25%) heat flow anomalies associated with hot-spot swells, but that our lack of understanding of the length scales over which fluid circulation redistributes the heat prevents any

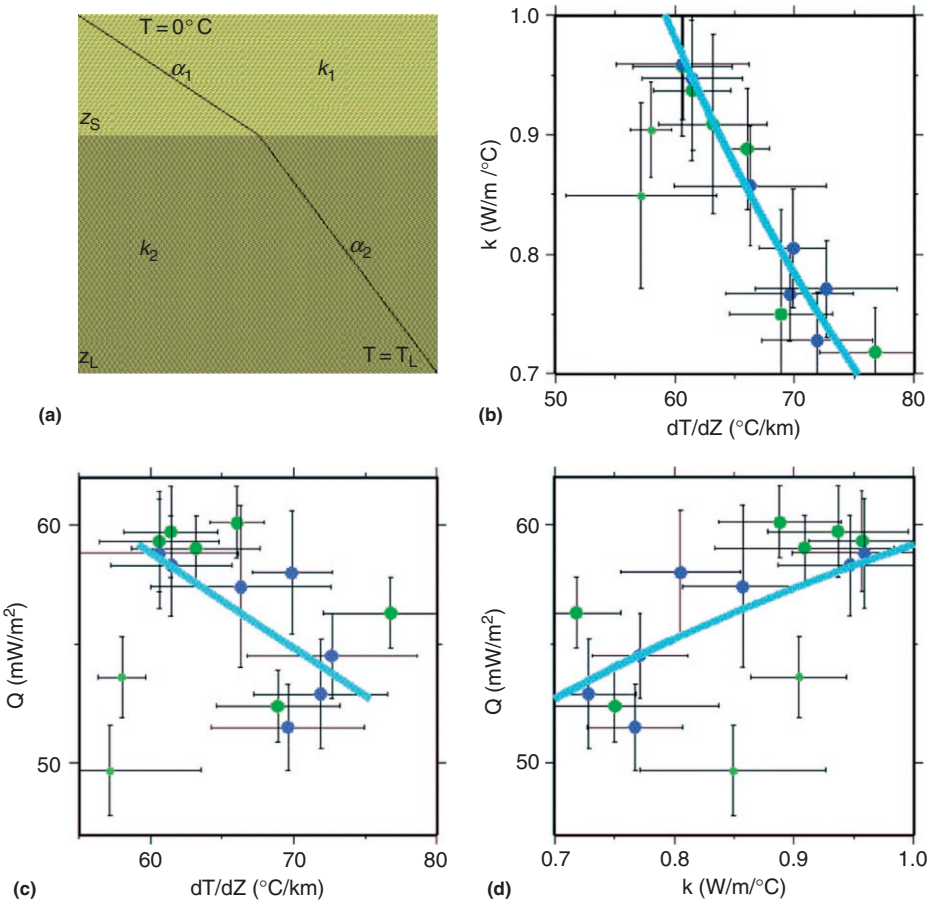

Figure 17 (a) Simple two-layer model for heat transport near the Hawaiian Islands. The upper layer of thickness z_s has thermal conductivity k_1 and temperature gradient α_1. The lower layer of thickness $(z_L - z_s)$ has a higher thermal conductivity k_2 and temperature gradient α_2. The lower boundary is maintained at an isothermal temperature T_L by fluid circulation. The upper boundary is maintained at temperature $T = 0$ °C by the ocean. (b) Plot of thermal conductivity k versus vertical temperature gradient dT/dz for the South Arch (blue dots) and Maro Reef (green dots). The blue line shows the least-squares best fit to the data as k_1 (equivalent to k in the observed data) is varied in the model in (a), excluding the two Maro Reef outliers shown as small dots. These outliers correspond to the measurements at $x = -177$ km and $x = 375$ km in **Figure 15**. (c) Same as (b), but for heat flow Q as a function of dT/dz (equivalent to α_1 in the model). (d) Same as (b), but for Q as a function of k. Reproduced from McNutt MK (2002) Heat flow variations over Hawaiian swell controlled by near-surface processes, not plume properties. In: Takahashi E, Lipman PW, Garcia MO, Naka J, and Aramaki S (eds.) *Geophysical Monograph Series, vol. 128: Hawaiian Volcanoes: Deep Underwater Perspectives*, pp. 365–372. Washington, DC: American Geophysical Union.

detailed picture of the spatial or temporal pattern for where and when that heat reaches Earth's surface.

1.14.4 Seismic Constraints on Crust and Lithosphere

The geophysical observations reviewed above provide but few constraints on how crustal and lithospheric structure is modified by hot spots. The depth anomalies of mid-plate swells require density reduction at depth, and the geoid height requires that low-density material to be below the mid-lithosphere in most cases. Heat flow evidence suggests that the low-density material is at least partially thermal in origin, although the effects of near-surface fluid circulation effectively mask much of the spatial and temporal pattern of any thermal disturbance. Geophysicists have therefore turned to seismology to better understand the deep structure of the Earth beneath hot spots and their swells. It is important to begin an investigation of hot spots from the top of the crust down into the lithosphere for at least two reasons. First, the surface structure is more accessible and can be probed using a number of seismic techniques, including active-source reflection and refraction, as well as imaging with passive arrays. Second, properly accounting for the effects of surface structure is necessary in nearly all geophysical analyses before determining what portion of the observed signal is of deep origin. Examples of crustal and lithospheric targets for seismic investigation, why they are important, and what has been learned are summarized in the succeeding text.

1.14.4.1 Sedimentary Structures

The largest hot-spot volcanoes are surrounded by massive volcaniclastic debris aprons that can exceed both the area and the volume of the intact volcanoes themselves (Moore et al., 1989). The slope failures which produce these landslide deposits occur many times during the period of active volcanism, and continue during the post-eruptive phase,

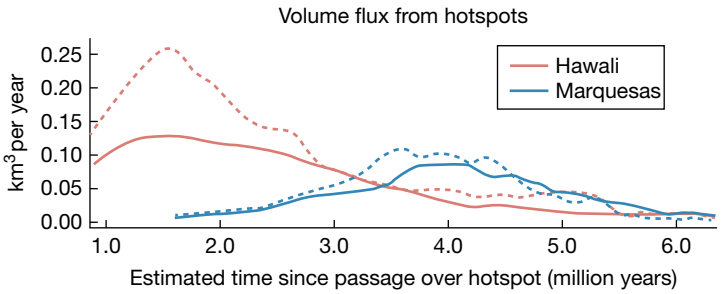

Figure 18 Volume flux of erupted volcanic rock as a function of time along the Marquesas and Hawaiian chains, as calculated from deflection models. Volcano names are shown for both chains at dated ages, with the Marquesan volcano names underlined. Solid lines are corrected for swell topography, dotted lines are uncorrected. Adapted from Filmer PE, McNutt MK, Webb HF, and Dixon DJ (1994) Volcanism and archipelagic aprons: A comparison of the Marquesas and Hawaiian Islands. *Marine Geophysical Research* 16: 385–406.

particularly if the volcano is not protected from the seas by a fringing coral reef. These post-eruptive sedimentary units provide a wealth of information on the history of a particular hot spot that is often more amenable to seismic imaging than is the volcanic edifice itself. In the oceans, these are well imaged by marine multichannel seismic data augmented with refraction data from sonobuoys or ocean-bottom seismometers (OBSs) to calibrate the velocity structure. In many cases, the value of the seismic data has been significantly enhanced by ocean drilling to provide accurate timelines through dating and other useful information, such as paleomagnetic chronology and paleoenvironmental history.

ten Brink and Watts (1985) obtained a seismic reflection image of the moat stratigraphy along a line crossing the Hawaiian chain and applied two-dimensional (2-D) modeling to determine whether the geometry of the reflectors contains any information on changes in elastic thickness that could be associated with the thermal evolution of the Hawaiian swell. In order to fit the apparent off-lap patterns in the stratigraphy, they assumed prolonged (>1 My) viscoelastic relaxation of the elastic plate. The cause of this relaxation of the elastic stresses would presumably be heat from the hot spot conducting through the lithosphere up the base of the elastic plate. If such an interpretation had been confirmed, it would have been good evidence for lithospheric thinning by the Hawaiian hot spot.

However, in a followup study, Watts and ten Brink (1989) demonstrated that a similar off-lap pattern could be produced in a 3-D model with progressive loading of the plate by new islands along the chain without requiring any temporal decrease in the stiffness of the elastic plate. Rees et al. (1993) acquired the definitive 3-D data set to test this hypothesis that the stratigraphic pattern in the Hawaiian moat was caused by sequential loading of volcanoes on an elastic plate of uniform elastic strength. Their single-channel reflection survey of the Hawaiian flexural moat imaged the sedimentary structures both across and along the strike of the chain between the islands of Hawaii and Kauai. They were able to explain the resulting stratigraphy in terms of competing effects of erosion/mass wasting, subsidence, and flexure. Significantly, Rees et al. (1993) did not require any temporal change in the elastic stiffness of the plate using a 3-D model. They noted that initially when a new volcano forms, the flexural moat is underfilled with sediment as the seafloor subsides beneath the weight of the new volcano faster than mass wasting can fill in the depression. Later, as volcano construction ceases and volcanic material is redistributed from the islands into the surrounding moat in major mass wasting events, the moat becomes filled, and in the case of older islands such as the Marquesas, overfilled such that the sediment surface in the moat slopes away from the volcanoes (Filmer et al., 1994). The gently sloping sedimentary blanket surrounding mature volcanoes has been termed an 'archipelagic apron' (Menard, 1956).

Seismic reflection images of the sedimentary debris that fills the flexural moats surrounding mid-plate hot-spot chains can also be used to estimate the volume of volcaniclastic sediments that must be added to the volume of the edifice itself in order to get an accurate estimate of the amount of melt produced by the hot spot. For example, the moat surrounding the Marquesas Islands is overfilled with 200 000 km^3 of volcaniclastic sediments with seismic velocities ranging from 4 to 5 km s^{-1} (Filmer et al., 1994). The acoustically chaotic core of the apron interior suggests that the moat fill consists primarily of debris flows from mass wasting events. Individual volcano collapse events can involve volumes exceeding 100 km^3 and may occur tens to hundreds of times during the life of a volcano. After accounting for the material filling the flexural moat, the Marquesas hot spot, during its peak activity at 3.5–5 Ma, was erupting nearly 0.10 km^3 of volcanic rock per year, which exceeded the rate of eruption of the Hawaiian hot spot during that same time period and is nearly as large as Hawaii's current rate for the past 1 My (**Figure 18**). The much larger apparent size of the Hawaiian volcanoes results from the fact that they load a stiffer elastic plate, are superimposed on a higher swell, and have not yet been as deeply eroded as the Marquesas Islands.

Watts et al. (1997) conducted a similar analysis for the Canary hot spot in the eastern Atlantic. Using multichannel seismic images from the flexural moat, they determined that 150 000 km^3 of material has been added above the preexisting surface of the flexed plate by the Canary hot spot, a number quite comparable to that for the Marquesas. The corresponding estimated magma generation rate, however, is only 0.006–0.02 km^3 per year on account of the much longer duration of the shield-building stage for the Canary volcanoes.

1.14.4.2 Volcanic Crust and Underplating

Hot-spot volcanoes, like all volcanoes, are built by the eruption of lavas on top of the preexisting crust. However, volcanism is

also associated with the interaction of the rising magma with the upper mantle and crust, including the emplacement of intrusive igneous rocks within the volcano, the crust below, and possibly the upper mantle. Consequently, constraints on the complete upper mantle and crustal structure are required to understand such basic aspects of hot spots as magmatic flux and lithospheric loading. Although modern marine seismic reflection systems that combine pneumatic sources with 3–6 km (or longer) arrays of hydrophone receivers are capable of imaging Moho in normal (~6-km-thick) oceanic crust, the thickened crust and rough topography of submarine volcanoes make seismic reflection methods inadequate to penetrate the full crustal structure of most oceanic volcanoes. The best full crustal models obtained to date at oceanic hot spots derive from seismic refraction experiments in which the sources and receivers are widely spaced and variations in seismic velocity are imaged.

Hawaii was the first hot spot to be investigated with deep-penetrating marine refraction data. Watts et al. (1985) and ten Brink and Brocher (1987) collected multichannel seismic reflection data and conducted several two-ship expanding spread profile (ESP) refraction experiments along a cross section of the Hawaiian swell near Oahu. Each ESP yielded a 1-D crustal seismic velocity model; used together, the ESP models comprise a 2-D cross section of the Hawaiian hot-spot trace. Unexpectedly, Watts et al. (1985) found that the center of the volcanic chain is underlain by a 4-km-thick and 200-km-wide subcrustal body with unusually high seismic velocity (7.4–7.8 km s^{-1}) for the lower oceanic crust (**Figure 19**). An apparent bifurcation of Moho was observed in the reflection profile on both sides of the volcanic edifice, bounding the high-velocity body. Watts et al. (1985), ten Brink and Brocher (1987), and Watts and ten Brink (1989) interpreted this unit as a deep crustal sill complex and Watts and ten Brink (1989)

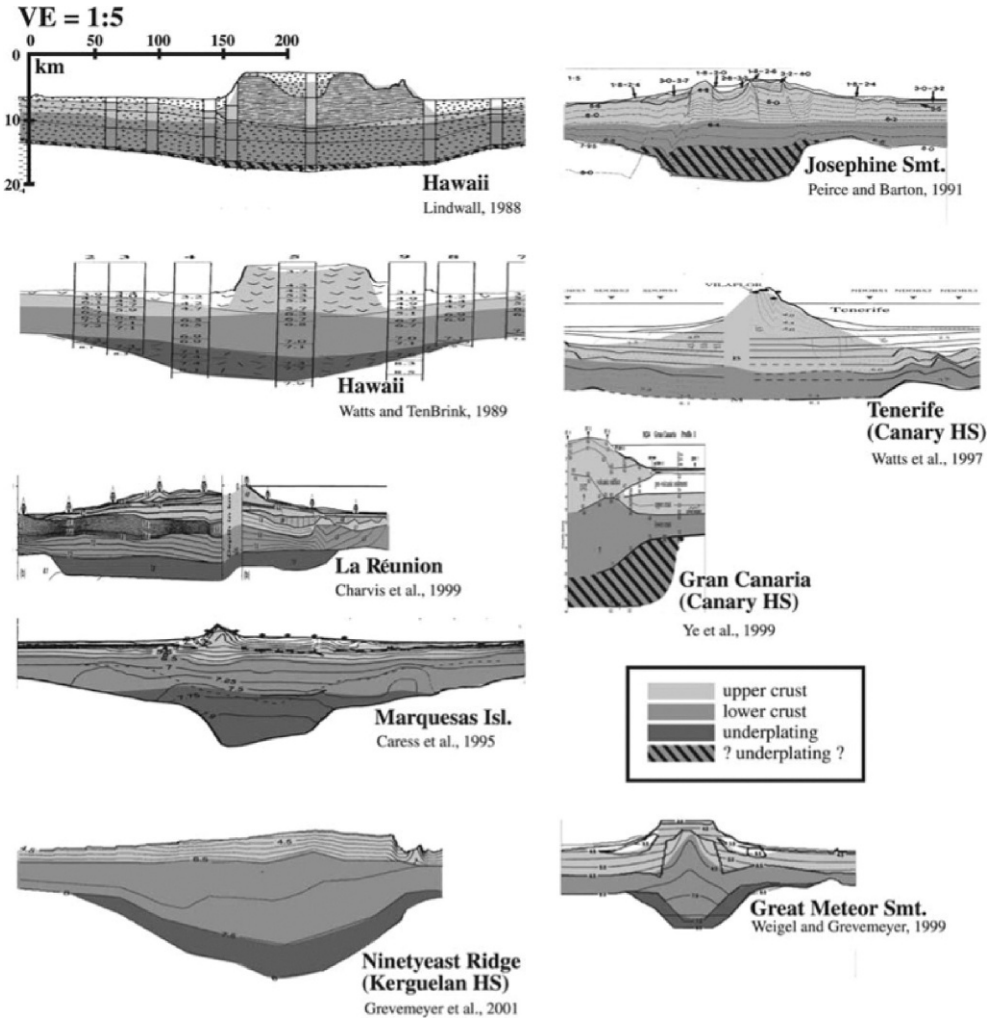

Figure 19 Compilation of several different hot-spot related volcanic structures imaged using seismic refraction and reflection data. All examples are scaled identically. Separation between upper and lower crust along all models is based only on velocities. Intrusive volcanism and underplating are characteristic for most of the volcanic provinces, which were located above a hot spot at the time of their formation. Reproduced from Kopp H, Kopp C, Phipps Morgan J, Flueh ER, Weinrebe W, and Morgan WJ (2003) Fossil hot spot–ridge interaction in the Musicians Seamount Province: Geophysical investigations of hot spot volcanism at volcanic elongated ridges. *Journal of Geophysical Research* 108. http://dx.doi.org/10.1029/2002JB002015.

referred to it as 'volcanic underplating.' The underplating interpretation was disputed by Lindwall (1988), who demonstrated that the critical ESPs beneath the center of the volcanic chain can also be reasonably fit by crustal models without a deep, high-velocity zone (**Figure 19**). More recent seismic refraction experiments at oceanic hot spots have used arrays of OBSs or ocean-bottom hydrophones (OBHs) as receivers, allowing for continuous 2-D or 3-D seismic velocity models that avoid the ambiguity inherent in the ESP refraction geometry.

Caress et al. (1995) obtained deep seismic reflection and high-quality refraction data beneath a second hot-spot chain, the Marquesas, and confirmed a second example of magmatic underplating. Three long MCS lines were located across the chain in gaps between the islands, and a refraction line using OBSs coincided with the central line. The multichannel seismic reflection data imaged the surface of the crust preexisting the eruption of the hot-spot volcanoes. The OBS refraction data imaged crustal arrivals constraining the velocity structure within the crust and also clearly imaged wide-angle reflections from the base of the preexisting crust, and, beneath the center of the volcanic chain, from a deeper interface. A 2-D tomographic inversion of the refraction and reflection arrival times demonstrated that a normal oceanic crustal structure lay beneath the Marquesas volcanoes, but was itself underlain by a large body with seismic velocities (7.5–7.9 km s^{-1}) intermediate between normal lower-crustal and upper-mantle values. The strength of the wide-angle reflections from the relict Moho and the base of the subcrustal body indicates that this magmatic underplating unit (**Figure 19**) is strongly distinct from both the preexisting crust above and the upper mantle below. Taking into account both the existing volcanic edifices and the material contained in the surrounding sedimentary apron, the underplated volume amounts to 1.9 times the volume erupted on top of the preexisting crust. Caress et al. (1995) proposed, based on analogies with results from refraction experiments in active continental rift zones (Benz and McCarthy, 1994; Jarchow et al., 1993) and on rifted continental margins (Holbrook and Kelemen, 1993), that this unit is an igneous intrusion or a mixture of intrusive rocks with preexisting mantle peridotites emplaced beneath the crust during the process of hot-spot volcanism. The seismic velocity of the underplated material suggests that the hot spot produced melt buoyant enough to rise through the upper mantle to the base of the crust, but not sufficiently buoyant to rise above the crust–mantle boundary.

The buoyant nature of the underplated material was confirmed by Wolfe et al. (1994), who demonstrated that a good fit to both the depth of the moat and the gravity anomaly over the Marquesas Islands requires that the underplated material flexes the elastic lithosphere from below. The combination of the seismic constraints on the volume of the underplating and the gravitational bound on its buoyancy yield an estimate of 3100 kg m^{-3} for the density of the underplated unit.

Since the initial studies of Hawaii and the Marquesas, several seismic refraction and reflection experiments have focused on the deep crustal structure of hot-spot traces emplaced on old lithosphere. The study sites include the Canary Islands (Dañobeitia and Canales, 2000; Watts et al., 1997; Ye et al., 1999), La Reunion (Charvis et al., 1999; Gallart et al., 1999), Great Meteor Seamount (Weigel and Grevemeyer, 1999), the Societies (Grevemeyer et al., 2001b), and the Cape Verde Islands (Ali et al., 2003). In all of these cases, refraction and/or reflection data are consistent with the existence of high-velocity regions in the deep crust or upper mantle suggestive of magmatic underplating (**Figure 19**). Leahy and Park (2005) have provided independent evidence of underplating associated with oceanic hot-spot volcanism by using teleseismic receiver-function analysis to investigate the crustal and upper-mantle structure of four Pacific islands: Hawaii, Kiribati, Raratonga, and Tahiti. At each of these hot-spot volcanoes, Leahy and Park (2005) find evidence for a high-velocity subcrustal body ranging from 2 km thick at Tahiti to 10 km thick at Raratonga.

In contrast to the oceanic islands constructed on old lithosphere, all but one of the seismic refraction studies of near-ridge hot-spot volcanism are consistent with crustal thickening without the formation of subcrustal underplating. These observations hold for discrete seamounts such as Ascension Island (Evangelidis et al., 2004) and the Musicians Seamounts (Kopp et al., 2003), for larger platforms such as Crozet Bank (Recq et al., 1998) and Iceland (e.g. Staples et al., 1997), and for very large aseismic ridges such as the Cocos Ridge (**Figures 9** and **10**; Walther, 2003) and the Carnegie Ridge (Sallares et al., 2005).

The one hot-spot trace combining a near-ridge origin with strong evidence for underplating is the Ninetyeast Ridge. In fact, the most complete, and highest-resolution, images to date of an oceanic underplating body were obtained by Grevemeyer et al. (2001a) at Ninetyeast Ridge. The underplated body has velocities of 7.5–7.6 km s^{-1} and is 325 km wide, emplaced beneath the entire extrusive edifice and extending 50 km further to the east. Beneath the center of the edifice the underplating is as much as 5 km thick (**Figure 19**). The underplated volume at Ninetyeast Ridge is nearly the same as that erupted surficially. Because the eastern side of the Ninetyeast Ridge coincides with a transform boundary created by the separation of Ninetyeast Ridge from Broken Ridge, the eastward extension of the underplating indicates that at least some of the underplating was emplaced long after the surficial extrusive eruptions. Grevemeyer et al. (2001a) thus proposed that the underplating was associated with late-stage volcanism.

Underplating has also been inferred at two LIPs, indirectly from gravity data at the Ontong Java Plateau (Ito and Taira, 2000) and from seismic refraction data at the Kerguelen Plateau (Recq et al., 1990). In the case of the Ontong Java Plateau, Ito and Taira (2000) interpreted the gravity data in terms of a larger elastic plate thickness for the subsurface load, suggesting that the underplating happened 40–100 million years after the eruption of the surface load at a time when the oceanic lithosphere was stiffer. This intriguing suggestion would place an important constraint on the duration of LIP-type volcanism by requiring the intrusion of a magma body long after the plate had drifted away from the original magma source. It would also have interesting implications for the vertical motion history of oceanic plateaus and could explain the subsidence deficit for Ontong Java as inferred from drill cores. However, the interpretation of the gravity data is not unique; large-scale lithospheric folding as Ontong Java encounters the Solomon trench could also explain the data (Ito and Taira, 2000). Deep seismic reflection and refraction data would be required to resolve the ambiguity.

It appears that magmatic underplating is a common, but not necessarily universal, feature of many types of hot-spot

volcanism. Underplating has mostly been found beneath oceanic volcanic structures emplaced in old, cold, and strong lithosphere. With the exception of Ninetyeast Ridge (Grevemeyer et al., 2001a), volcanic edifices formed in the thin, weak lithosphere near spreading centers do not show evidence for underplating. However, at least some of the Ninetyeast Ridge underplating was emplaced after the edifice had moved away from the near-ridge environment. Although the refraction, reflection, and gravity data from Hawaii (Watts and ten Brink, 1989) and Ninetyeast Ridge (Grevemeyer et al., 2001a) suggest that underplating may be associated with later stages of hot-spot volcanism, the existence of underplating beneath the currently volcanically active La Reunion (Charvis et al., 1999; Gallart et al., 1999) demonstrates that subcrustal intrusions can occur during the primary edifice-building stage of hot-spot volcanism. More comprehensive experiments providing multiple cross sections of active oceanic hot spots, such as the Hawaiian Islands, will be required to determine the relationship between the onset of surficial volcanism and the development of an underplated complex.

1.14.4.3 Mantle Lithosphere

Imaging the mantle lithosphere beneath hot spots in order to study the formation of swells or superswells has been one of the highest-priority experiments for distinguishing among different models for swell formation, but also one of the most difficult experiments in terms of obtaining a robust result. Given the lack of specificity in swell-height data as to the location of the low-density buoyant support, the ambiguity in interpretation of geoid data in terms of isostatic or dynamic uplift models, and the concern that surficial fluid circulation could mask the signal of the hot spot in heat flow data, seismic data hold the most promise for determining whether the support for mid-plate swells lies in the mantle lithosphere, as predicted by the lithospheric thinning model, or beneath it, and whether the compensation is buoyant because it is hot or by virtue of its mineralogy.

The two principal methods for seismically probing the mantle lithosphere have been to use array processing on direct teleseismic arrivals at dense clusters of seismometers and differencing short-period surface waves between favorably positioned stations. The Hawaiian swell and Iceland have been the principal foci for this type of seismic investigation, although the MELT experiment yielded some information on the South Pacific superswell (MELT Scientific Team, 1998), and the PLUME project (Suetsugu et al., 2005) should provide further constraints soon.

Laske et al. (1999) obtained a year-long record of Rayleigh-wave phase velocities at periods between 15 and 70 s for more than 70 earthquake events by deploying an array of ocean-bottom differential pressure gauges along the southern edge of the Hawaiian swell. The information was inverted to determine the average seismic velocity structure beneath the array, which did not depart significantly from the average for 100 Ma lithosphere. However, they did detect a strong lateral velocity gradient across the array, with velocity decreasing within 300 km of the island chain. A more expansive array experiment is currently underway to obtain a more complete image of the seismic velocity structure in the mantle lithosphere beneath the Hawaiian swell.

Collins et al. (2002) used a different approach for constraining the structure of the mantle lithosphere beneath the Hawaiian swell. Using data from two broadband seismometers deployed a few hundred kilometers southwest of Oahu, they observed P-to-S converted phases from the Gutenberg discontinuity, thought to correspond to the base of the lithosphere. They place the base of the lithosphere at 80 km depth, in agreement with the results from Rayleigh-wave dispersion studies (Priestley and Tilmann, 1999; Woods and Okal, 1996). In contrast to the results of Laske et al. (1999), the results from these studies do not point to differences between the thickness and velocity structure of the lithosphere beneath the Hawaiian swell as compared with the parameters for normal oceanic lithosphere of that age. Ideally, the results from the ocean-bottom array experiment currently in progress will settle this controversy with major implications for the origin of hot spots and their geophysical signatures.

Several major field programs and tomographic studies have been devoted to the Iceland hot spot (Allen et al., 2002; Bijwaard and Spakman, 1999; Ritsema et al., 1999; Wolfe et al., 1997). Seismic analyses that have been conducted in Hawaii to detect any hot-spot-induced anomalies within a high-velocity lid make no sense in Iceland, which coincides with a mid-ocean ridge, where by definition the lithosphere tends toward zero thickness. Quite independent studies agree that the upper mantle immediately beneath Iceland is anomalously slow seismically, even by mid-ocean ridge standards, to about 400 km depth, consistent with the presence of high-temperature upwelling mantle. The real controversy for Iceland centers on whether the seismic velocity anomaly extends deeper than the mantle transition zone (Foulger et al., 2001; Helmberger et al., 1998). Converted phases mapped beneath Hawaii (Li et al., 2000) and Tahiti (Niu et al., 2002) also point to unusually warm upper-mantle temperatures immediately beneath those hot spots, although not for the South Pacific superswell in general.

Earthquake seismology has also found some applications in hot-spot research near the locus of active volcanism. Wolfe et al. (2003) used an improved relocation technique to demonstrate that earthquakes at $\sim$30 km depth in the mantle lithosphere beneath Hawaii define a seaward-dipping, low-angle fault plane, rather than a magma conduit through the lithosphere as had been previously suggested.

Whole-earth tomography has also made some contribution in this area, but in the past has lacked the resolution in the upper 100 km to unambiguously image the lithosphere and in the rest of the mantle to detect the possible signature of mantle plumes. New data-processing techniques (e.g., Capdeville et al., 2002; Montelli et al., 2004) hold the promise for directly imaging plumes within the mantle. For example, a recent study by Lei and Zhao (2006) uses ten converted seismic phases to image slow P-wave velocities extending from the surface to the CMB beneath Hawaii (**Figure 20**). However, Lei and Zhao's data set provides limited resolution because there are few crossing raypaths, and their models depend strongly on assumed CMB structure, indicating that further effort is required to refine CMB models. The results from various studies have yet to converge. For example, using the criterion that a plume must show continuous low shear velocity in the upper mantle, Ritsema and Allen (2003) find only eight hot spots

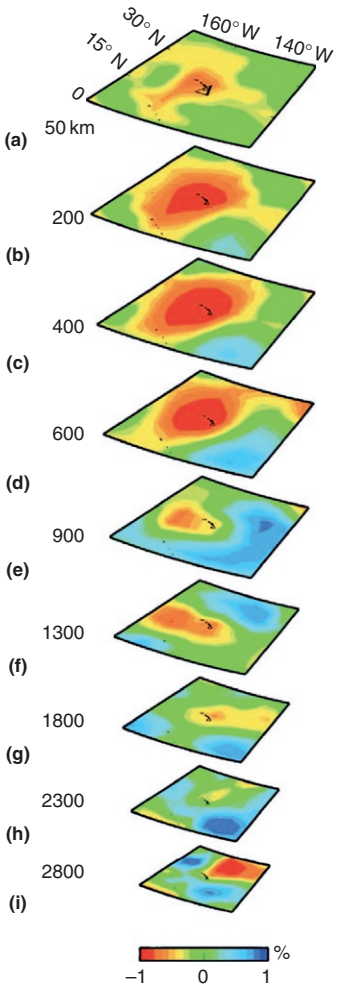

Figure 20 P-wave tomographic images in map view around the Hawaiian hot spot. The depth of each layer is noted on the left. Red and blue colors denote slow and fast velocities, respectively, compared to the IASP91 1-D Earth model (Kennett and Engdahl, 1991). Reproduced from Lei J and Zhao D (2006) A new insight into the Hawaiian plume. *Earth and Planetary Science Letters* 241: 438–453, with permission from Elsevier.

(Afar, Bowie, Easter, Hawaii, Iceland, Louisville, McDonald, and Samoa), out of the 37 considered, that pass the test for plume origin. Montelli et al. (2004), on the other hand, use the criterion that there must be seismic evidence that P-wave velocity lows extend from the upper mantle into the lower mantle. Their list of hot spots with plume origin includes only Ascension, Azores, Canary, Easter, Samoa, and Tahiti. Only Easter and Samoa are common on both lists. Courtillot et al. (2003), using broader criteria based on seismological, other geophysical, and helium isotope data, conclude that Afar, Easter, Hawaii, Reunion, Samoa, Louisville, Iceland, and Tristan are likely to be of plume origin. At this point in time, consensus seems to emerge that plume-like behavior is responsible for Easter and Samoa, with conflicting views on the appropriateness of this theory for other hot spots.

1.14.5 Conclusions

1.14.5.1 Emerging View on Geophysical Structure of Hot Spots and Swells

Hot-spot volcanism is clearly an important global phenomenon that reflects deep-Earth processes, modifies much of the lithosphere over time, and thus significantly impacts the thermal and chemical evolution of the Earth. Progress in the understanding of hot spots has required the integration of many types of geophysical observations, including bathymetry, satellite altimetry, gravity, heat flow, seismic reflection, seismic refraction, and teleseismic data. The results that heat flow patterns can be dominated by lateral variations in thermal conductivity and fluid circulation and that some, but not all, intraplate volcanic features include high-seismic-velocity underplating demonstrate that the shallow structure of hot-spot features must be well understood before the mantle structures related to the causes of hot-spot volcanism can be reliably resolved.

Recent studies of oceanic hot spots and hot-spot swells have explored multiple plausible mechanisms for producing intraplate volcanism, particularly including mantle plumes and lithospheric cracking due to plate-scale stresses. Plume theory remains viable, but only a small number of hot spots appear associated to deep-mantle plumes, and the nature of the plumes remains very much in question. The observed variety and complexity in the setting, history, and structure of intraplate volcanic features likely reflects multiple causes for hot-spot volcanism.

1.14.5.2 Promising Areas for Further Research

We anticipate that future geophysical hot-spot research will include more comprehensive seismic crustal and Moho imaging of active volcanic features to understand how hot-spot volcanism modifies preexisting crust over time. We also expect considerable effort to achieve better resolution of lateral variations in seismic velocity in the mantle by taking advantage of additional computational resources and improving knowledge of the complex crustal and upper-mantle structure. However, improvements in the coverage provided by the global seismic networks will be vital, particularly including long-term ocean stations in the deep-ocean basins.

1.15.1 Introduction

Controlled-source seismic methods are used widely at small, medium, and large scales for investigating the Earth from the shallow subsurface (upper tens of meters) to structures in and below the continental lithosphere (a few to a few hundred kilometers depth). Also called active-source seismology, controlled-source seismology requires the timed release of mechanical energy to generate elastic wavefields. For investigation as deep as the upper mantle, the mechanical energy is generated by the release and conversion of chemical energy (occasional use has been made of nuclear explosions, particularly in the former Soviet Union). Marine investigations of the crust and top of the mantle commonly utilize the release of pressurized air, whereas on land, oscillating masses at the surface are used. For shallow investigations (tens to hundreds of meters depth), the sources include gunshots, weight drops, hammer blows, oscillating masses, and small explosives. Generally, the seismic data are recorded on fairly dense arrays of portable seismic instruments, also referred to as seismic channels, numbering in the hundreds to thousands or even tens of thousands.

The most widely used application of controlled-source seismology is the reflection seismic method employed in the exploration for petroleum. Seismic surveys, processing, and interpretation account for the bulk of petroleum exploration budgets prior to drilling. Recently, the mining industry has employed seismic reflection and refraction methods for investigating the extent of known ore bodies and for identifying fault zones along which economically viable mineralization has occurred. At smaller scales, both reflection imaging and refraction velocity analysis are used in geotechnical and engineering applications, groundwater resource assessment, and environmental investigations.

In this chapter, we confine our attention to controlled-source investigations used primarily to determine structure of the crust and upper mantle. There is considerable overlap between experimental methods used in academic investigations and those used in the various industries.

1.15.2 Vertical-Incidence and Wide-Angle Seismology

Controlled-source imaging of the lithosphere can be divided into two main areas: (1) near-vertical reflection methods and (2) refraction/wide-angle reflection methods. We assume that the reader is familiar with Snell's law of reflection and refraction at an interface separating two materials with different seismic velocities and the reflection and transmission coefficients that describe the partition of motion during the interaction. Reflection and transmission coefficients depend on contrasts in seismic impedances, the product of seismic velocity, c, and density, ρ, as well as the incidence angle, θ. An important point in the behavior of a reflected and refracted wave occurs at the critical angle, θ_c, the incidence and reflection angle in the slower medium at which the wave in the faster medium refracts parallel to the interface with a refraction angle of $\pi/2$ taken from the normal to the interface. In the Earth, velocity generally increases with depth, producing critical refraction at different angles depending on depth. Reflection coefficients in the 'precritical' regime, $\theta < \theta_c$, are typically small and real $(R(\theta < \theta_c) < 0.1)$, whereas those in the 'postcritical' regime are of order 1 and can be complex $(R(\theta < \theta_c) = |R(\theta)|\exp(i\phi(\theta)), |R(\theta)| \sim 1, \phi \neq 0)$ producing large reflections and distorting the waveform (see Aki and Richards, 2002, Chapter 5). There are a number of important distinctions between the two methods that include data-acquisition geometry and hence the completeness of the wavefield recorded and analyzed, the approach used to make an image of the Earth, and the meaning and resolution of the final image. The first concerns the maximum distance between source location, x_s, and receiver location, x_r, during recording compared to the maximum experiment target depth, z_{max}. The distance between the source and receiver, $x_s - x_r$, is referred to as the source–receiver offset or just the offset; in the coordinate system we are using, x is the location in 3-space, z is the vertical coordinate, positive down, and x_s and x_r are the positions of the source and receiver, usually at or near the Earth's surface. Reflection seismology normally uses waves that travel further vertically than horizontally:

$$\max|(x_s - x_r)/z_{max}| \leq 1 \qquad [1]$$

Reflection seismology directly uses the reflected or backscattered wavefield to form an image of the 'reflectivity structure.' Reflectivity structure is the vertical derivative of seismic impedance normalized by its average value. For a layered medium, this is proportional to the reflection coefficient at normal incidence calculated as a continuous function of depth. Seismic waves arrive at subhorizontal interfaces with small, precritical incidence angles, giving small real reflection coefficients $(0.1 \leq R)$. The data to be analyzed are the precritical backscattered wavefield (Figure 1). Reflection processing is based on the common midpoint (CMP) method, combined with an image formation step based on one of various formulations of the wave equation to yield a reflectivity map that ideally corresponds to the Earth's 'impedance structure.' For whole-crust studies, the customary frequency band of interest is 8–60 Hz.

In contrast, the wide-angle method relies on the identification of first-arriving refracted waves and large-amplitude postcritical reflections where

$$\max|(x_s - x_r)/z_{max}| \gg 1 \qquad [2a]$$

and, usually,

$$\max|(x_s - x_r)/z_{max}| > 5 \qquad [2b]$$

In very densely recorded wide-aperture surveys, precritical reflections can be identified and used as well. Data analysis typically employs a model-based approach, such as traveltime inversion, to yield a spatial map of 'seismic velocity.' For lithospheric studies, the typical frequency band of interest is 1–20 Hz. This approach is variously referred to as the refraction method, wide-angle method, or refraction/wide-angle reflection method. For brevity, we use the terms wide-angle data and wide-angle method (a more precise term would be wide aperture).

The two conventional controlled-source methods are essentially end-members: Reflection data provide a high-resolution structural image, and the wide-angle data provide a lower-resolution velocity model. The difference in resolution scales between the two methods is generally more than an order of magnitude. Hybrid methods that combine the reflection and wide-angle approaches are gradually evolving, as we will describe later.

Figure 1(a) shows a two-dimensional (2-D) model of crustal P-wave velocity structure (Hole et al., 2005) used to generate viscoelastic synthetic seismograms for testing various analysis methods. Figure 1(b) is a vertical-component synthetic shot gather illustrating the main arrival types (phases or events) used in traveltime and amplitude modeling of wide-angle data. Often, only the first-arrival times are modeled; these correspond to the Pg and Pn arrivals before and after the Pg/Pn crossover point (~140 km in Figure 1(b)). Although the wide-angle wavefield can be complicated, as in this synthetic example, identifying and modeling the arrival times of first arrivals and prominent reflections, such as from the Moho (PmP), is a much more robust and less-demanding problem than modeling the full wavefield (described in Section 1.15.21). Figure 1(c) and 1(d) shows the same shot but at offsets to ±25 km with and without the Pg and Rayleigh waves. Figure 1(d) shows the wavefield that would be processed to form a reflection image. Numerous reflections are visible from within the crust and as deep as the Moho.

1.15.3 Background

We begin with a few background equations relevant to both reflection and refraction seismologies. We consider a wave operator, L, for the 3-D inhomogeneous wave equation:

$$LG(x, x_s, t) = \delta(t)\delta(x - x_s) \qquad [3]$$

where G is Green's function for either the acoustic wave equation or one of the elastic wave potentials (see Aki and Richards (2002, p. 64)). For a constant coefficient equation, that is, a constant velocity medium, the solution is

$$G(x, x_s, t) = \frac{1}{4\pi c^2}\frac{\delta(t - |x - x_s|/c)}{|x - x_s|} \qquad [4]$$

where c is the material velocity. Here, the spreading is the reciprocal distance between the observation point and the

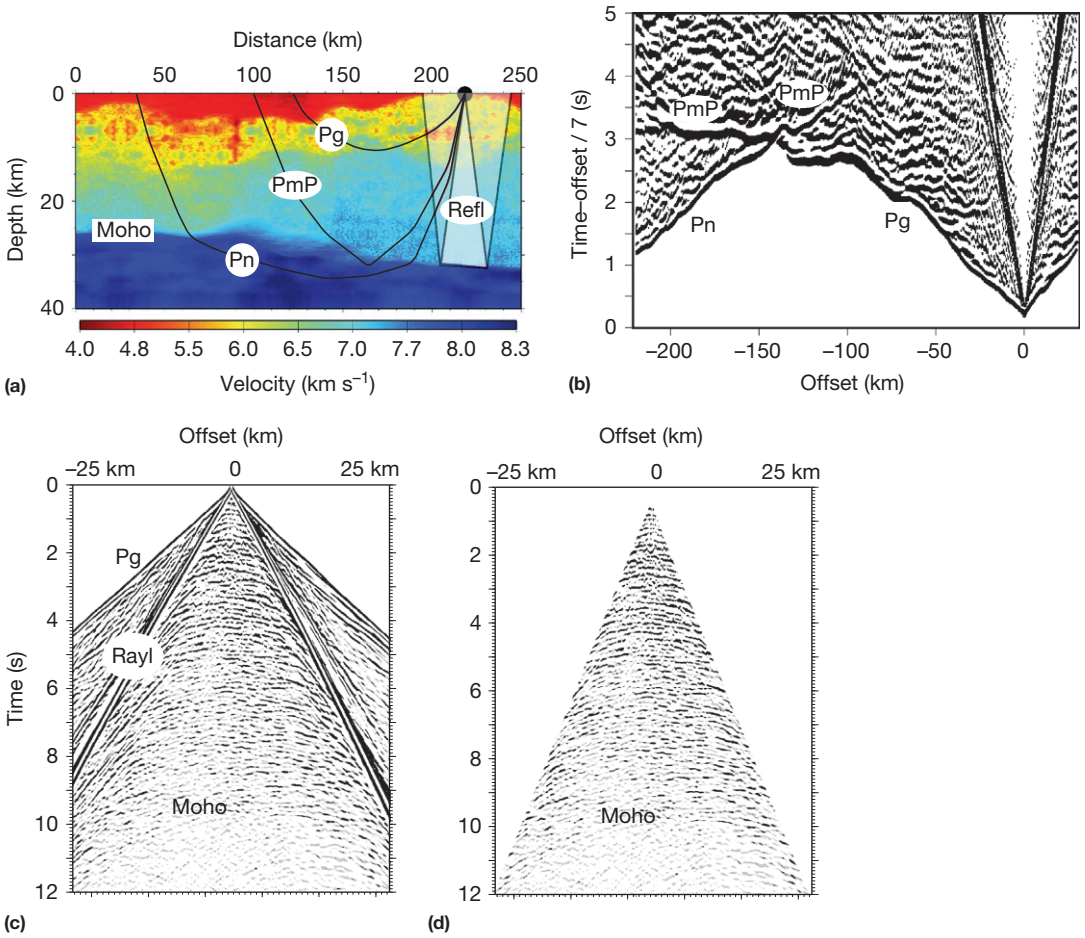

Figure 1 Example of phases used in crustal reflection and wide-angle studies. (a) Synthetic crustal P-wave velocity model from Hole et al. (2005) and representative ray paths for main phases: Pg – crustal refraction; PmP – Moho reflection; Pn-upper-mantle refraction. Refl – the area sampled by reflection data from this shot. Source location indicated by black dot. (b) Vertical component, viscoelastic full-wavefield data for source location indicated in (a). Phases are labeled corresponding to those in (a); both precritical PmP and postcritical PmP are visible. Time is reduced by 7 km s^{-1}, which means a correction equal to offset/7 km s^{-1} is applied. Phases with velocity of 7 km s^{-1} will appear horizontal. (c) The same shot record showing 25 km offset around the shotpoint. The Pg phase and Rayleigh waves are visible in the record, as well as converted shear waves. All of this energy is considered noise in the reflection model. A series of reflection events appear with hyperbolic shape inside the Rayleigh wave cone. (d) The same shot record with the noise field zeroed out. This is the part of the wavefield used for reflection imaging. In conventional reflection acquisition, each receiver point has a small array of geophones, which is used to suppress the Rayleigh waves, increasing the size of the region from which reflection data can be recovered.

source point, x_s, and the delta function is delayed by that distance divided by the medium velocity. For a variable velocity medium, one of the commonly employed solutions is to introduce a high-frequency approximation with a similar form as the constant velocity solution:

$$G(x, x_s, t) \approx a(x, x_s)\delta(t - \tau(x - x_s)) \quad [5]$$

Here, $a(x, x_s)$ is the geometric optics amplitude resulting from spreading, and again, the delta function carries the time dependence. Equation [5] is valid only in the absence of caustics. The traveltime obeys the 'eikonal' equation:

$$|\nabla\tau| = \frac{1}{c(x)} \quad [6]$$

The eikonal equation can be integrated along the path of the wave through the medium:

$$\tau(x, x_s) = \int_{x_s}^{x} \frac{dl(x, x_s)}{c(l)} \quad [7]$$

The distance l is the ray connecting x_s to x. Much of reflection and refraction seismologies are based on numerical implementations of these equations. We develop eqns [5] and [6] for the acoustic equation in the section on reflection seismology. Equation [7] is the starting point for the discussion on wide-angle analysis methods.

1.15.4 Reflection Seismology

The goal of this section is to provide an understanding of the theoretical basis of reflection seismology, rather than a comprehensive literature review. Because reflection seismology is

the principal petroleum exploration tool and is now also an important tool in oil field management, the reflection seismology literature is extremely large, highly specialized, and heavily laden with commercial jargon. We have tried to minimize the jargon but still introduce enough common terminology so that the reader can consult the journals of the Society of Exploration Geophysicists, *Geophysics*, and the European Association of Exploration Geophysicists, *Geophysical Prospecting*, and understand much of the seismic literature.

Reflection experiment geometries are designed to produce as regular a sampling of the subsurface as possible. The receiver geometry is usually fixed relative to and moves with the source point. In the marine environment, this is accomplished by towing an air gun source array and one or multiple linear arrays of pressure sensors behind the acquisition vessel. On land, vertical-component geophones are deployed in linear or areal arrays to record signals from accelerated weight drops, explosive charges, or vibrating masses on trucks, a source known as Vibroseis™. For efficiency on land, the acquisition requires that about twice as many geophones are deployed on the ground as are recording at a given time. As the source point moves, different parts of the seismic array are turned on and off to maintain a constant recording aperture, a practice called 'roll-along' recording.

For a variety of pragmatic reasons, wave propagation and imaging in reflection seismology are normally based on a scalar, acoustic wave equation. For the forward and inverse problems, we follow a development for solution of the wave equation from a set of course notes by Symes, as this development illustrates imaging with the backscattered wavefield and allows us to describe traditional reflection seismology. For a 3-D medium having laterally and vertically variable density and sound speed,

$$\begin{aligned} &\frac{1}{\rho(x)c^2(x)}\frac{\partial^2 p(x,\,t)}{\partial t^2}-\nabla\cdot\left[\frac{1}{\rho(x)}\nabla p(x,\,t)\right]=f(t)\delta(x)\\ &c(x)=\sqrt{k(x)/\rho(x)} \end{aligned} \qquad [8]$$

where $p(x,t)$ is the pressure field, $\rho(x)$ is mass density, $c(x)$ is the sound speed, $\kappa(x)$ is the bulk modulus, and $f(t)$ is a temporally dependent, but spatially localized source field.

We assume that the sound speed can be decomposed into a low wave number, smoothly varying term $c_0(x)$ and a rapidly varying component $\delta c(x)$. Similarly, we can separate the density field and the pressure fields into background and perturbed fields:

$$\begin{aligned} c(x)&=c_0(x)+\delta c(x)\\ \rho(x)&=\rho_0(x)+\delta\rho(x)\\ p(x,\,t)&=p_0(x,\,t)+\delta p(x,\,t) \end{aligned} \qquad [9]$$

The scale separation is designed to produce kinematically correct traveltimes and approximately correct geometric optics amplitudes by solving for a solution to the smooth background field but is also designed so that the detailed dynamics (amplitudes) result from terms scaled by perturbed material properties. We term the former field the smooth velocity model, and the latter, with velocity scaled by density, the acoustic impedance, $i(x)$. Estimating the smooth velocity field from seismic data is one of the principal challenges in seismic reflection imaging, and for the imaging problem, this field is termed the 'migration velocity model.' The spatial variation of the impedance normalized by the average impedance is the reflectivity, $r(x)$, which provides the most basic high-frequency image of the subsurface (i.e., the details in $r(x)$ are considerably higher-resolution details than the details in $c_0(x)$):

$$\begin{aligned} i(x)&=c(x)\rho(x)\\ i(x)&\approx c_0(x)\rho_0(x)+\delta c(x)\rho_0(x)+\delta\rho(x)c_0(x)\\ r(x)&=\frac{\delta i(x)}{i_0(x)}=\left[\frac{\delta c}{c_0}+\frac{\delta\rho}{\rho_0}\right] \end{aligned} \qquad [10]$$

There are few analytic guidelines quantifying what constitutes smooth and rapidly varying in the scale separation. Numerical experiments on the Marmousi synthetic model (see Versteeg, 1994) suggest that the migration velocity model needs to be specified at about three times the dominant wavelength in the illuminating wavefield to provide an accurate migration model. This is restrictive in a complicated model. For many places in sedimentary basins, a quasilinear velocity increase with depth is a reasonable estimate of $c_0(x)$. A reasonable approximation for the crystalline crust is the velocity field determined by a refraction profile that has been interpreted using the regularized inversion methods discussed in the following section.

Substituting the perturbed quantities into [8] and solving for $\delta p(x,\,t)$ to first order gives

$$\frac{1}{\rho c^2}\frac{\partial^2\delta p}{\partial t^2}-\nabla\cdot\frac{1}{\rho}\nabla\delta p=\frac{2\delta c}{\rho c^3}\frac{\partial^2 p(x,\,t)}{\partial t^2}-\frac{1}{\rho}\nabla\cdot\left[\frac{\delta\rho}{\rho}\nabla p\right] \qquad [11]$$

We can develop a solution for $\delta p(x,\,t)$ from solutions for $p(x,\,t)$. Let $G(x_s,\,x,\,t)$ be Green's function for the solution of the inhomogeneous equation

$$\begin{aligned} &\frac{1}{\rho(x)c^2(x)}\frac{\partial^2 G(x_s,\,x,\,t)}{\partial t^2}-\nabla\cdot\frac{1}{\rho(x)}\nabla G(x_s,\,x,\,t)\\ &\quad=\delta(t)\delta(x-x_s) \end{aligned} \qquad [12]$$

where x_s is the source position and x the observation position. The solution $p_0(x_s,\,x,\,t)$ is given by integrating G against the extended time source:

$$p_0(x_s,\,x,\,t)=\int dt' f(t-t')G(x_s,\,x,\,t) \qquad [13]$$

Estimating $f(t)$, termed the source wavelet, has a long history in exploration geophysics and is still a research topic. Early developments in statistical communication theory are the most widely used methods for reshaping the source pulse to a spike or relatively flat band-limited function. The reader is referred to landmark books by Robinson and Treitel (1980) and Claerbout (1976) and the practical processing text by Yilmaz (2001). These pulse estimation and reshaping methods are termed statistical, spiking, and predictive deconvolution. They have been applied very successfully to receiver-function processing in teleseismic seismology.

For constant velocity, the solution to eqn [12] is given by eqn [4]. For a smoothly variable velocity, we develop an asymptotic solution by assuming a progressive wave expansion of the form

$$u(x_s, x, t) = a(x, x_s)S(t - \tau(x_s, x)) + R(x_s, x, t) \quad [14]$$

where $S(x_s, x, t)$ is assumed to have the same order of singularity as constant velocity Green's function and the remainder, R, is smoother than S. Substituting [14] into [12] gives

$$\begin{aligned}\left[\frac{1}{\rho c^2}\frac{\partial^2}{\partial t^2} - \nabla\cdot\frac{1}{\rho}\nabla\right]u &= \frac{a}{\rho}\left[\frac{1}{c^2} - |\nabla\tau|^2\right]S''(t-\tau) \\ &+ \frac{1}{\rho}\left[2\nabla\tau\cdot\nabla a - \left(\nabla\tau\cdot\frac{\nabla\rho}{\rho} + \nabla^2\tau\right)a\right]S''(t-\tau) \\ &+ \left[\nabla\cdot\frac{1}{\rho}\nabla a\right]S(t-\tau) + \left[\frac{1}{\rho c^2}\frac{\partial^2 R}{\partial t^2} - \nabla\cdot\frac{1}{\rho}\nabla R\right]\end{aligned} \quad [15]$$

If the coefficients of the four terms on the right vanish, then u satisfies the acoustic wave equation. The order of singularity decreases term by term on the right-hand side, so that if

$$\frac{1}{c^2} - |\nabla\tau|^2 = 0 \quad [16]$$

and

$$2\nabla\tau\cdot\nabla a - \left(\nabla\tau\cdot\frac{\nabla\rho}{\rho} + \nabla^2\tau\right)a = 0, \quad [17]$$

the solution is approximately correct in high-frequency components. Equation [16] is the eikonal equation of geometric optics, with $\tau(x, x_s)$ the traveltime field, and eqn [17] is the transport equation, with $a(x, x_s)$ the geometric optics amplitude field. Both of these quantities can be solved numerically for laterally and vertically variable media of some complexity by either ray tracing or finite differences (e.g., Cerveny et al., 1977; Van Trier and Symes, 1991; Vidale, 1988, 1990). In analogy to constant coefficient Green's functions solution, we can write approximate Green's function solution as

$$G(x_s, x, t) \cong a(x, x_s)\delta(t - \tau(x, x_s)) \quad [18]$$

This suffices for the 'incident' field and the direct wave when applied against the source function $f(t)$. To solve for the backscattered field, that is, the field of interest in reflection seismology, we find the perturbed field $\delta p = f * \delta G(x_s, x, t)$ by solving

$$\frac{1}{\rho_0 c_0^2}\frac{\partial \delta G}{\partial t^2} - \nabla\cdot\frac{1}{\rho_0}\nabla\delta G = \frac{\delta c}{\rho_0 c_0^3}\frac{\partial^2 G}{\partial t^2} - \frac{1}{\rho_0}\left(\nabla\frac{\delta\rho}{\rho_0}\right)\cdot\nabla G \quad [19]$$

Let the acoustic wave operator be denoted L, and apply Green's formula

$$\int_V dx \int dt[(Lu)v] = \int_V dx \int dt[u(Lv)] \quad [20]$$

with $u = G$ and $v = \delta G$. At this point, we want to specify the observation point, x_r, measure time with respect to the observation coordinate, t_r, and so make use of the identity

$$\begin{aligned}\delta G(x_s, x_r, t_r) = \int_V dx \int dt[&\delta G(x_s, x_r, t) \\ &\times \delta(x - x_r)\delta(t - t_r)]\end{aligned} \quad [21]$$

Substituting and rearranging [20] gives

$$\begin{aligned}\delta G(x_s, x_r, t_r) = \int_V dx \Bigg[&\frac{2\delta c(x)}{\rho_0(x)c_0^3(x)}\frac{\partial^2 G(x_s, x, t)}{\partial t^2} \\ &- \frac{1}{\rho_0(x)}\left(\nabla\frac{\delta\rho(x)}{\rho_0(x)}\right)\cdot\nabla G(x_s, x, t)\Bigg] \\ &\times G(x_s, x_r, t_r)\end{aligned} \quad [22]$$

This is a very general expression for the perturbation field, which is referenced to the shot and receiver coordinates, and the receiver timescale. For calculations, we substitute approximate 3-D Green's function [18]:

$$\begin{aligned}\delta G(x_s, x_r, t_r) \sim &\frac{\partial^2}{\partial t_r^2}\int_V \frac{dx}{\rho_0(x)}\Bigg[a(x_r, x)a(x_s, x) \\ &\times \left\{\frac{2\delta c(x)}{c_0^3(x)}\right\}\delta(t_r - \tau(x_r, x) - \tau(x_s, x))\Bigg] \\ &+ \frac{\partial}{\partial t_r}\int_V \frac{dx}{\rho_0(x)}\Bigg[a(x_r, x)a(x_s, x) \\ &\times \left\{\nabla\frac{\delta\rho(x)}{\rho_0(x)}\cdot\nabla_x\tau(x_s, x)\right\}\delta(t_r - \tau(x_r, x) - \tau(x_s, x))\Bigg] \\ &- \int_V \frac{dx}{\rho_0(x)}\Bigg[a(x_r, x)a(x_s, x)\left\{\nabla_x a(x_s, x)\cdot\nabla\frac{\delta\rho(x)}{\rho_0(x)}\right\} \\ &\times \delta(t_r - \tau(x_r, x) - \tau(x_s, x))\Bigg]\end{aligned} \quad [23]$$

Note that the terms in braces, containing material property fluctuations, are coefficients in integral equations having the same basic form. This expression can be used for Kirchhoff forward modeling of the backscattered field. If density is a constant, the expression reduces to

$$\begin{aligned}\delta p(x_s, x_r, t_r) = &\frac{\partial^2}{\partial t_r^2}\int_V \frac{dx}{\rho}\Bigg[a(x_r, x)a(x_s, x)\left\{\frac{2\delta c(x)}{c_0^3(x)}\right\} \\ &\times f(t_r - \tau(x_r, x) - \tau(x_s, x))\Bigg]\end{aligned} \quad [24]$$

$$\begin{aligned}\delta p(x_s, x_r, t_r) = &\int dw(-\omega^2)\exp(-i\omega t_r) \\ &\times \int_V \frac{dx}{\rho_0}\left[a(x_r, x)a(x_s, x)\left\{\frac{2\delta c(x)}{c_0^3(x)}\right\}\right] \\ &\times f(\omega)\exp(i\omega(\tau(x_r, x) + \tau(x_s, x)))\end{aligned}$$

The coefficient scaling the amplitude and phase terms contains the reflectivity function $r(x) \sim \delta c(x)/c_0(x)$. Both integrals show the two phase factors corresponding to traveltimes to and from the scattering point.

For illustration, we can simplify the equations by assuming that $c =$ constant everywhere, that δc is nonzero at $x = (x_1, y_1, z_1)$ within the integration volume, and that $\rho =$ constant everywhere. Perturbation Green's function is

$$\begin{aligned}\delta G(x_s, x_r, x, t) = &\frac{2\delta c}{c_0^3\rho_0}\frac{\delta''(t - (R_s + R_r)/c)}{16\pi^2 R_s R_r} \\ R_s = &\sqrt{(x_{s1} - x_1)^2 + (x_{s2} - y_1)^2 + (z_s - z_1)^2} \\ R_r = &\sqrt{(x_{r1} - x_1)^2 + (x_{r2} - y_1)^2 + (z_r - z_1)^2}\end{aligned} \quad [25]$$

Applying the source wavelet against [25] gives

$$\delta p(x_s, x_r, x, t) = \frac{2\delta c}{c^3\rho}\frac{f''(t - (R_s + R_r)/c)}{16\pi^2 R_s R_r} \quad [26]$$

1.15.5 The CMP Method in Reflection Seismology

Traditional reflection seismology is based on the coordinate transformation:

$$\begin{aligned}m &= (x_s + x_r)/2 \\ b &= (x_s - x_r)/2\end{aligned} \quad [27]$$

where m is the midpoint coordinate, the average position of the source and receiver, and h is the half-offset, which measures the source and receiver distance away from the midpoint. This methodology was patented in 1950 by W. H. Mayne who called it the common depth point method. Reflection data acquisition is designed so that all the midpoints have an equal number of seismograms with a nearly identical and full range of offsets and azimuths. Populating the midpoint locations uniformly requires very regular data-acquisition geometries.

Traditional reflection seismology makes use of properties of the midpoint–offset domain to form the simplest form of backscattered image (Figure 2). The outstanding properties of this coordinate system are that (1) for any plane interface and scattering point, the traveltime curves are symmetrical in offset around any midpoint, with the minimum at $b = 0$ (Figure 2(c)); (2) for constant velocity, the traveltime curve for a flat reflector is a hyperbola expressed in offset and the 'two-way zero-offset traveltime' $t_0 = 2z_0/c_0$; and (3) many types of multiple reflections are strongly attenuated relative to primary reflections.

The symmetry of the traveltime curve allows us to estimate $t_0(m = \text{constant})$, and the hyperbolic form of the traveltime curve allows us to estimate the medium velocity using multiple $b(m = \text{constant})$ values. This is the most rudimentary form of velocity analysis to find c_0. Expressing [26] in midpoint and offsets gives

$$\begin{aligned}\delta p(m, b, t_r) &= \frac{2\delta c f''(t - 2R/c)}{c^3\rho \quad 16\pi^2 R^2} \\ \delta p(m, b, t_r) &= \frac{2\delta c f''(t - (t_0(z_0) + \Delta t_{NMO}(z_0, b)))}{c^3\rho \qquad 16\pi^2 R^2}\end{aligned} \qquad [28]$$

where $R = \sqrt{(b^2 + z_0^2)}$, $t_0 = 2z_0/c$, $\Delta t_{NMO} = 2R/c - t_0$, where Δt_{NMO} is called the 'normal moveout (NMO) time.' For fixed m, the traveltime curves are symmetrical in h around $b = 0$. For any horizontal reflector in a background velocity dependent only on depth, $c_0(z)$, the traveltime curve can be approximated as a hyperbola that is parameterized by the zero-offset time and a time (depth)-dependent velocity to second order in the ratio h/z. This velocity is called the 'root mean square (rms) velocity' (Dix, 1955). The rms velocity is interpreted as the velocity that gives the set of straight ray, approximate, traveltimes closest to the actual curved ray-path traveltimes for a given depth. The rms velocity at a given depth is always less than the true velocity above that depth. Characterization of the traveltime curve as a hyperbola expressed in two-way traveltime and offset coordinates is true for any reflecting plane regardless of dip and azimuth, but the physical meaning of the derived velocities becomes increasingly obscure.

Correcting the traveltime by the difference between the hyperbolic time at offset h and that at t_0, termed the 'normal moveout' correction (Figure 2(d)), gives a vertical focusing principle. This aligns the arrivals on all the seismograms at a CMP allowing them to be summed, or 'stacked,' to enhance signal to noise. If each midpoint has N individual seismograms at different $b(m = \text{constant})$ and if the noise field is random in time and space, the theoretical signal-to-noise improvement by stacking is $N^{1/2}$. N is referred to as the 'fold,' or redundancy of the data. The collection of seismograms at a CMP is termed a 'gather.' The seismograms can be sorted, or 'gathered,' into any common coordinate. The original seismic record of all seismograms for one shot is referred to as a shot gather. All the shots recorded by one receiver are a receiver gather, and all seismograms from all shots and receivers at a single offset are called a common offset gather.

The 'CMP stacked section' is an approximation to a zero-offset section. The 'zero-offset' section would be the image formed by making measurements along the surface with a coincident source and receiver. One of the most important steps in making the CMP stacked section is estimating $c(z)$, or $c_{rms}(z)$, known as 'velocity analysis.' Taner and Koehler (1969) introduced the velocity spectrum, in which CMP data are summed using a 'spectrum' of different trial velocities for NMO correction at each depth. The velocity giving the maximum power in the stack at a given depth is chosen as correct.

The CMP stacked section was the first widespread imaging technique for the subsurface that made direct use of the recorded seismograms (Figure 3(a)). For a quasilayered medium, it provides a very accurate representation of the subsurface, but as it lacks a horizontal focus, the images of laterally variable structures are distorted in a number of predictable ways.

1.15.6 Migration

The true power of imaging with reflection data emerged when computationally efficient expressions for the backprojection and horizontal focusing of the field δp were developed, allowing highly detailed images of geologic structures to be made in media with laterally variable velocity, $c_0 = c_0(x_1, x_2, z)$. Migration, most simply, increases lateral resolution by collapsing diffractions from points and edges and restores continuous reflections from dipping structures to their 'true' dips and positions, the fidelity of 'true' depending on the approximations used (see Yilmaz, 2001). 'Time migration' makes use of constant or fairly smoothly varying velocity and backpropagates along straight rays (Figure 3(b)), whereas 'depth migration' attempts to reposition energy along estimates of the true travel paths and provides a mapping from time to depth (Figure 3(c) and 3(d)). The former is much less expensive computationally than the latter. These methods require a propagation operator and an imaging condition. The literature on the former is large, while the development of the imaging condition, as well as a class of backpropagation operators, is largely attributed to Claerbout (1970, 1971, 1976, 1985).

To start, let us expand what we mean by an image of the subsurface. The CMP section is an image that provides only a vertical focus. Scales (1995) provided a useful definition of an image that is a frequency sum at a point, x, in the subsurface

$$I(x) = S_{PP}(x) = \int_{-\infty}^{\infty} d\omega \left[F_1(\omega) \frac{\delta p_{ref}(x, x_r, \omega)}{p_{inc}(x_s, x, \omega)} \right] \qquad [29]$$

With this definition, the image is the acoustic scattering coefficient formed by dividing the field recorded at x_r backpropagated to x, by the field incident on x from x_s. The position x is now called a common image point, or a common reflection point. The collection of data migrated to that point for a variety of (x_r, x_s) is a common image gather (CIG; Al-Yahya, 1989).

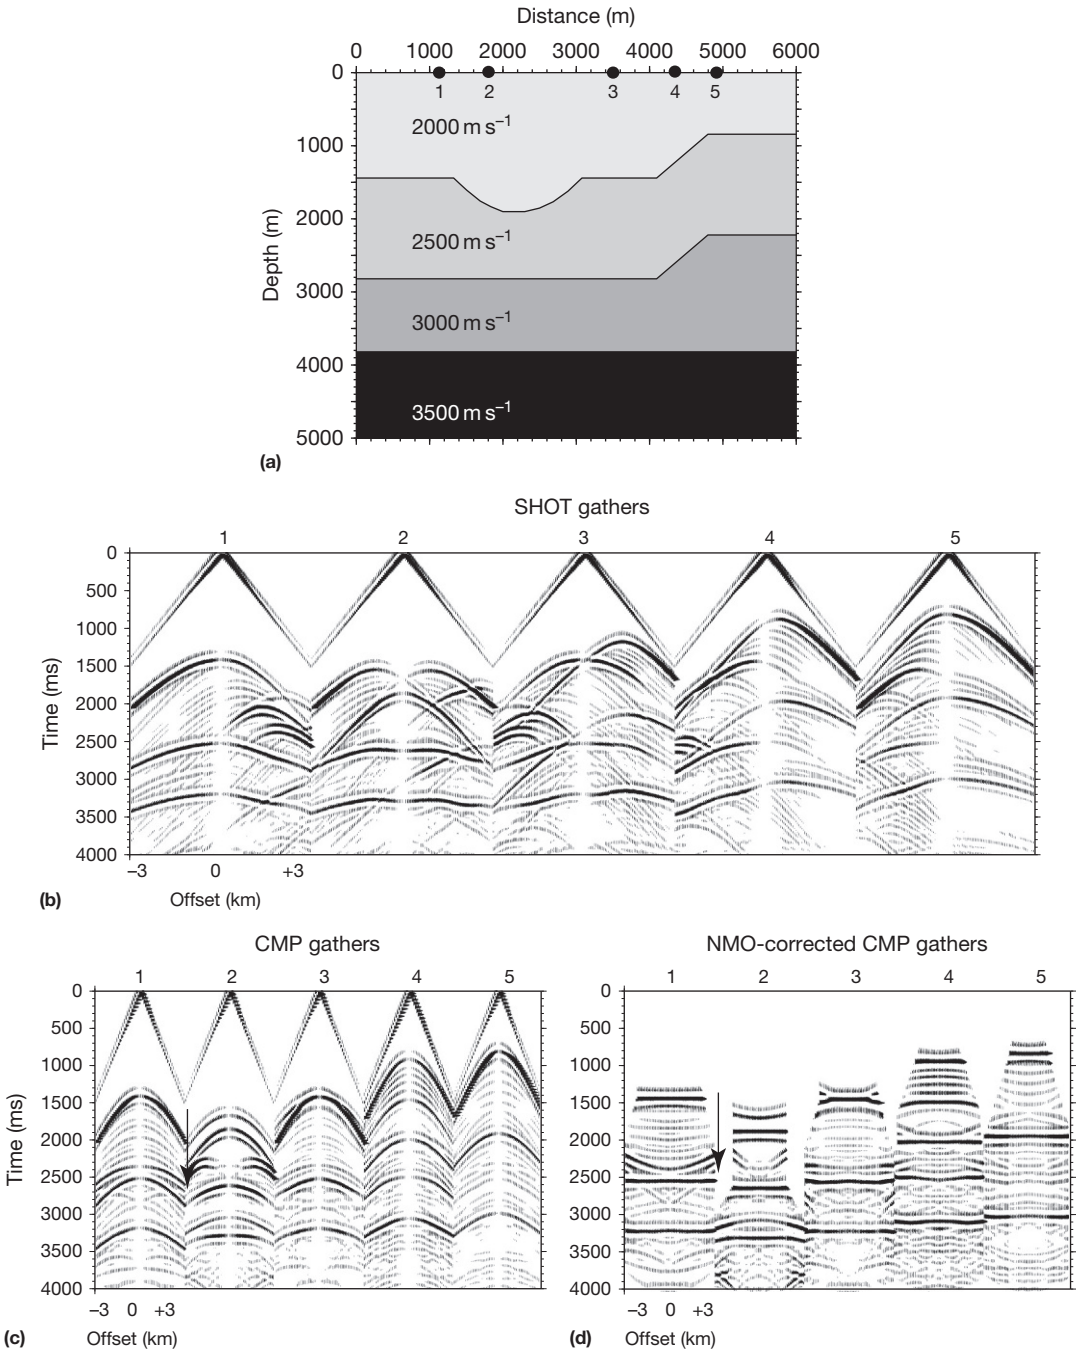

Figure 2 Synthetic reflection data set calculated with an acoustic finite-difference wave equation code. (a) The finite-difference velocity model with locations of the shot and CMP gathers that are shown in the following panels (locations 1–5). (b) Five of several hundred shot records showing the complex reflection patterns originating from laterally variable layering. (c) CMP gathers from five locations along the velocity model. In the midpoint–offset domain, the traveltimes are symmetrical about $b = 0$. (d) Vertical focus provided by normal moveout correction to the CMP gathers with the direct wave zeroed. The NMO correction was made using the local rms velocities. Note that the NMO correction fails to flatten events arriving at the same zero-offset time but having different phase velocities, that is, conflicting dips (arrows in (c) and (d)).

$F_1(\omega)$ is a shaping filter that takes into account the finite bandwidth of the source. This is a particularly easy image to form, as it makes direct use of the recorded data $\delta p(x_s, x_r, t)$, requiring only that we backpropagate it to the scattering point, x, to form $\delta p(x, x_r, t)$. For $\delta p(x_s, x, t)$, we can either estimate the incident field or propagate the source field; if we choose the latter, note that both δp and p contain $f(t) => F(\omega)$ and the source wavelet is theoretically removed automatically. In this case, $F_1(\omega)$ is used to stabilize the division, but in practice, filtering and deconvolution processing is employed prior to migration. Backpropagating both source and receiver wavefields is termed 'shot–geophone prestack migration.' In this

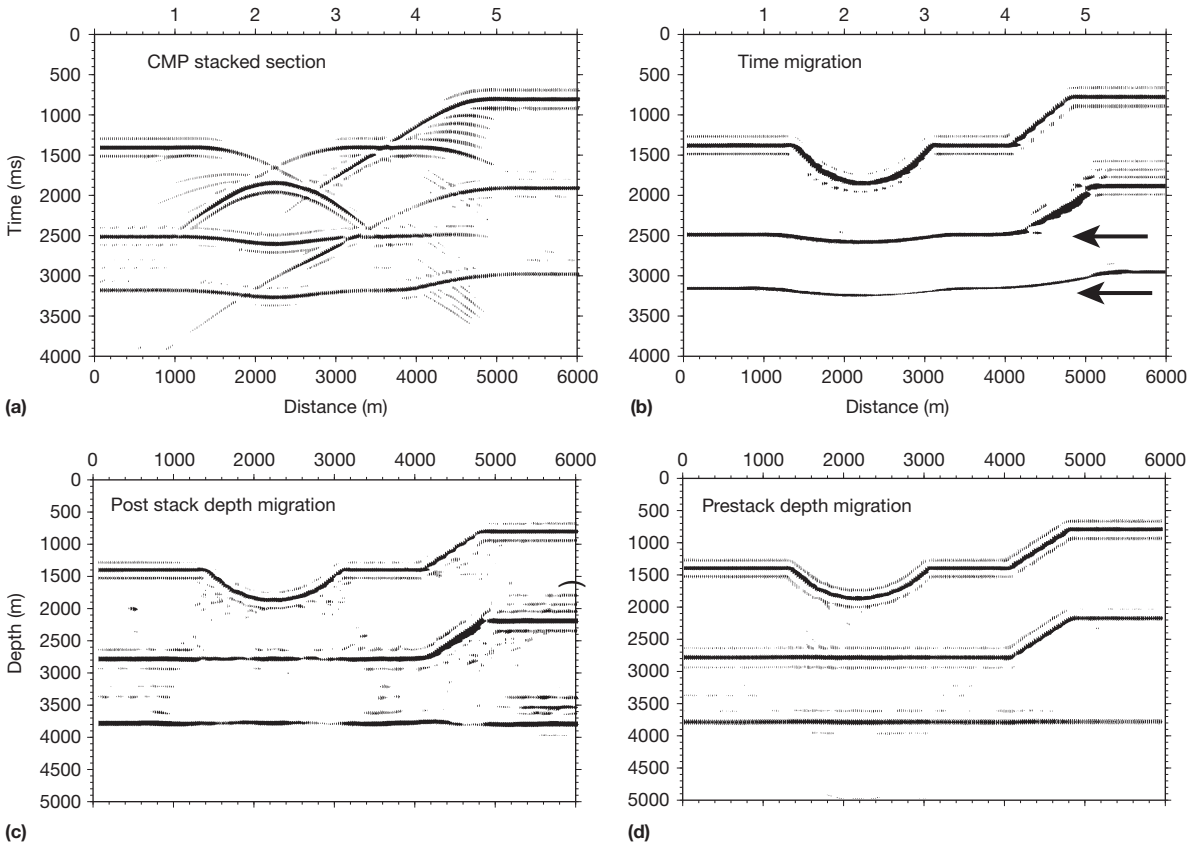

Figure 3 Processed synthetic data from the model in **Figure 2**. (a) The CMP stacked section shows distortions resulting from the lack of a lateral focus. Note particularly the caustic from the bowl-shaped feature in the shallowest interface at location 2 and the large diffractions from locations 2 to 4 from the dipping portions of the two shallowest interfaces. (b) Time migrating the CMP stacked section removes the distortion of the caustic but fails to flatten the two deeper horizons (arrows). (c) Poststack depth migration flattens the deeper reflectors but fails to illuminate them uniformly. (d) Prestack depth migration produces the clearest image; note the lack of amplitude fluctuation in the deepest horizon. Prestack migration operates on the original data without the intermediate step of NMO correction and stacking and provides both horizontal focusing and vertical focusing simultaneously. All the migrations were done with Kirchhoff algorithms similar to those described in the text.

case, the scattering coefficient is implicitly dependent on the incidence–reflection angle. Data compression, summing the redundant data reflected from x, is done as the last step. The scattering coefficient as a function of incidence angle can be extracted prior to summation by examining CIGs. We can also prestack migrate the data in the midpoint–offset domain, termed 'constant offset prestack migration,' by fixing h and migrating the data at different offsets independently. This has a number of desirable qualities that make it a common form of prestack migration.

In the CMP stacked section, $b = 0$, and midpoint is the migration coordinate. This is termed 'poststack migration' and is much less expensive than prestack migration because the data are compressed by the CMP fold prior to migration. However, poststack migration loses the angular dependence of the scattering coefficient and has other problems as well.

1.15.6.1 Imaging Condition

The imaging condition takes a form appropriate to the numerical implementation of the backpropagation operator, but in its simplest form, it is the negative of the time that backscattered energy on the seismic record took to get there, that is, it is equal to the time that the scattered field takes to propagate back to the scattering object plus the time the incident field takes to propagate from the source to the scattering point. This is termed time reversal.

1.15.6.2 Backpropagation Operators

We will continue with the asymptotic form for the backscattered field to describe seismic migration, but we note that entirely numerical approaches, that is, finite-difference methods, mixed finite-difference Fourier transform, and Fourier transform methods using the full-wave equation and various approximations to the one-way wave equation, are also widely used (e.g., Claerbout, 1970, 1985; Gazdag, 1978; Stolt, 1978).

Here, we develop an intuitive approach to migration of the precritical field $\delta p(x_s, x_r, t)$ using the Kirchhoff integral (e.g., Gardner et al., 1974 and Schneider, 1978) and the high-frequency formulation described earlier. We write the wave equation in the frequency domain for the smooth model and, for simplicity, consider constant density:

$$\left[\frac{-\omega^2}{\rho_0 c_0^2(x)}-\frac{1}{\rho_0}\nabla^2\right]u(x,\omega)=0$$
$$\left[\frac{-\omega^2}{\rho_0 c_0^2(x)}-\frac{1}{\rho_0}\nabla^2\right]G(x_s,x,\omega)=-4\pi\delta(x-x') \quad [30]$$

These are Helmholtz equations that can be substituted into a form of Green's theorem to isolate u, the field at x':

$$\begin{aligned}\int_V dx\left[u\nabla^2 G-G\nabla^2 u\right]&=\int_S ds(x_0)\left[u\frac{dG}{dn}-G\frac{du}{dn}\right]\\&=\frac{-1}{4\pi\rho_0}\int_S ds(x_0)\left[u(x_0,\omega)\frac{dG(x_0,x',\omega)}{dn}\right.\\&\quad u(x',\omega)\\&\quad\left.-G(x_0,x',\omega)\frac{du(x_0,\omega)}{dn}\right]\end{aligned} \quad [31]$$

This integral has a simple interpretation: the field anywhere in a volume can be described by measurements of the field and its derivative on the surface bounding it. This forms the basis for several migration operators and is widely used in diffraction theory (e.g., Goodman, 1996; Sommerfeld, 1954). Generally, we have only a recording of the field or its derivative, so we choose a kinematically correct Green's function that makes one of the two terms in [31] vanish on S. Green's function is then an auxiliary field; it does not necessarily solve the physical problem for u. Let the surface S be defined by $z=0$, and choose a Green's function that vanishes on S by introducing a mirror source in the region $z<0$. We can combine the asymptotic form of free-space Green's function with a copy of its mirror source. Since the normal n is positive outward, at $z=0$, the two sources cancel:

$$\begin{aligned}G_f(x,x',t)&\cong a(x',x)\delta(t-\tau(x,x'))\\G_f(x,x',\omega)&=a(x',x)\exp(i\omega\tau(x,x'))\\G_f(x_0,x',\omega)&=a(x',x^+)\exp(i\omega\tau(x^+,x'))\\&\quad -a(x',x)\exp(i\omega\tau(x^-,x'))\\G(x_0(z=0),x',\omega)&=0\end{aligned} \quad [32]$$

where x^+ and x^- refer to fields approaching $z=0$ from below and above. The normal derivative of Green's function becomes

$$\frac{dG}{dn}=2\frac{dG_f}{dn}\bigg|_{z=0} \quad [33]$$

Substituting this into the diffraction integral

$$u(x',\omega)=\frac{-1}{2\pi}\int_S ds(x_0)\times\left[u(x_0,\omega)\frac{dG_f(x_0(z=0),x',\omega)}{dn}\right] \quad [34]$$

Evaluating the normal derivative of G gives

$$\begin{aligned}\frac{dG}{dn}&=\frac{da(x_0,x')}{dn}\exp(i\omega\tau(x_0,x'))\\&\quad+a(x_0,x')i\omega\frac{d\tau}{dn}\exp(i\omega\tau(x_0,x'))\\\frac{d\tau}{dn}&=|\nabla_{x_0}\tau(x_0,x')|\cdot n\\\frac{d\tau}{dn}&=\frac{1}{c_0(x_0)}\cos(\theta(x_0))\end{aligned} \quad [35]$$

We can further simplify the diffraction integral by assuming that the derivative of amplitude is much smaller than that of phase and neglect the first term. This gives the Rayleigh–Sommerfeld diffraction integral

$$u(x',\omega)\cong\frac{-1}{2\pi\rho_0}\int_S ds(x_0)\left[u(x_0,\omega)a(x',x_0)\frac{(i\omega)\cos\theta(x_0)}{c_0(x_0)}\times\exp(i\omega\tau(x_0,x'))\right] \quad [36]$$

The integral [36] was developed for a flat surface but is approximately true for a surface that undulates around $z=0$ with spatial frequency small compared to that of the wavefield. The latter is known as the Kirchhoff approximation (Beckman and Spizzichino, 1963). If we let $u(x_0,\omega)=\delta p(x_0,\omega)$, the back-scattered field recorded at the surface, we can inverse Fourier transform to get

$$\begin{aligned}&\frac{1}{2\pi}\int d\omega\left[\delta p(x,\omega)\exp(-i\omega t)\right]\\&\cong\frac{-1}{4\pi^2\rho_0}\int_S ds(x_0)\int d\omega\left[\delta p(x_0,\omega)a(x_0,x')\right.\\&\quad\left.\times\frac{\cos\theta(x_0)}{c_0(x_0)}\exp(-i\omega(t-\tau(x',x_0)))\right]\end{aligned} \quad [37]$$

The integrand consists of known quantities, with the traveltime and amplitude field of Green's function determined from the smooth velocity field. The diffraction integral looks very much like Scales' definition of a seismic image [29]. The differences from the image definition are that the spreading function is reversed in sense (i.e., this formulation is for forward, not reverse propagation) and the integrand is not scaled by the incident field and the pulse shaping filter. Let $x'=x$, and let $x_0=m$ be the midpoint coordinate for $b=0$. We can modify the integral for poststack imaging, using Green's function to estimate the amplitude of the incident field at x:

$$p(x;m,b=0)=a(x;m,b=0) \quad [38]$$

Dividing both integrands gives

$$\begin{aligned}&\frac{1}{2\pi}\int d\omega\left[F_1(\omega)\frac{\delta p(x,\omega)}{p(x;m)}\exp(-i\omega t)\right]\\&\cong\frac{-1}{4\pi^2\rho_0}\int_S ds(m)\int d\omega(i\omega)\left[\delta p(m,\omega)B(x,m,\omega)\right.\\&\quad\left.\times\frac{\cos\theta(m)}{c_0(m)}\exp(-i\omega(t-2\tau(x,m)))\right]\end{aligned} \quad [39]$$

where we have doubled the traveltime field to account for downward propagation and B restores the spreading from the surface midpoint coordinate to the scattering point and contains the pulse shaping filter:

$$B(x,m,\omega)=\frac{F_1(\omega)}{a^2(x,m)} \quad [40]$$

This integral can be used for poststack migration of the CMP stacked section, or a zero-offset section. By invoking the imaging condition in the Fourier integral, $(t-2\tau(x,m)=0)$, the field δp is backpropagated and focused when its time is equivalent to the zero-offset two-way traveltime:

$$I(x) = \frac{-1}{4\pi^2\rho_0}\int_S \mathrm{d}s(m)\int \mathrm{d}\omega(\mathrm{i}\omega)\left[\delta p(m,\omega)B(x,m,\omega) \times \frac{\cos\theta(m)}{c_0(m)}\exp(-\mathrm{i}\omega(t-2\tau(x,m)))\right]_{t=2\tau} \quad [41]$$

The imaging condition makes the frequency integral just a sum over frequency. The integral can be interpreted in two ways. If we fix x, a single point in the image space, the integral sums all $\delta p(m, t = 2\tau(x = \text{constant}, m))$ values in the data space along the two-way traveltime curve from x to all midpoints. For constant velocity, this is a sum over a hyperboloid. If we fix m, the single point in data space $\delta p(m = \text{constant}, t = 2\tau(x, m) = \text{fixed})$ is spread over a surface in x at the distance corresponding to traveltime $2\tau(x, m)$. For constant velocity, this is a spherical shell in image space. This is termed poststack Kirchhoff migration (**Figure 3(c)**) and can be in time or depth, depending on whether we assume straight or curved rays.

For prestack depth migration, we can apply the integral [39] twice and invoke the reciprocity principle, with one surface integral over the shot coordinate and the other over a common receiver coordinate (e.g., Wiggins, 1984; **Figure 3(d)**), to give

$$I(x) = \frac{-1}{8\pi^3\rho_0^2}\int_S \mathrm{d}s(x_\mathrm{s})\int \mathrm{d}s(x_\mathrm{r})\int \mathrm{d}\omega(-\omega^2) \times \delta p(x_\mathrm{s}, x_\mathrm{r}, \omega)B_1(x, x_\mathrm{s}, \omega)B_2(x, x_\mathrm{r}, \omega) \times \left[\frac{\cos\theta(x_\mathrm{s})\cos\theta(x_\mathrm{r})}{c_0(x_\mathrm{s})c_0(x_\mathrm{r})} \times \exp(-i\omega(t-\tau(x,x_\mathrm{s})-\tau(x,x_\mathrm{r})))\right]_{t=\tau(x,x_\mathrm{s})+\tau(x,x_\mathrm{r})} \quad [42]$$

Integrating over the shot surface may seem counterintuitive; however, it is a simple matter to sort the data into receiver gathers. This integral also can be simply rewritten in the midpoint–offset coordinates by substituting [27]. Data manipulations are somewhat easier in midpoint–offset coordinates, and more importantly, the edge effects introduced from the finite apertures in the receiver and shot spaces are mitigated.

1.15.7 Reflection Seismology Examples

Interesting reflection seismology examples abound in a literature that now spans more than four decades. Readers are referred to the *American Association of Petroleum Geologists Bulletin* and the *Geological Society of America Bulletin* for general applications in geology and to *Geophysics* and *Exploration Geophysics* for methodology. The development of deep crustal reflection seismology is documented in the volumes from the proceedings of the International Symposia on Deep Crustal Reflection Profiling, published by the American Geophysical Union and *Tectonophysics*.

We conclude this section by presenting some academic applications of active-source seismic investigations. Many of the Earth's great Cenozoic mountain belts now have one or more deep crustal seismology profiles across them, as do paleomountain belts and modern and ancient extensional terranes. The different types of plate boundary zones have now been studied using reflection and refraction seismology. The few examples we show here are particularly interesting for either their experimental method or their broader Earth science significance.

In Northern Canada, the Canadian Lithoprobe program has imaged a Proterozoic thrust belt to an unusually great depth that shows subducting slab(s) of ocean lithosphere frozen into the Precambrian lithosphere (**Figure 4**; Bostock, 1998; Cook et al., 1999). The seismic data were acquired with Vibroseis™ sources using standard industry reflection equipment and a total recording spread of about 24 km.

This image is extraordinary for a number of reasons. It suggests that thrust stacking of oceanic lithosphere can be a means to stabilize and grow the continents, a long-standing problem in early the Earth's development. This and similar images also suggest that some mountain belts are formed by a process termed wedge tectonics in which some or all crustal layers are thrust upward over a strong crustal wedge and are then eroded. Mantle layers subduct beneath the crustal wedge and can be accreted to the lithosphere inboard of the subduction zone. Another interesting aspect of this image is the appearance of numerous thrust faults extending to the Moho, implying that brittle behavior extended to Moho depths, requiring either very high strain rates, an unusually cold orogen, or unusual crustal rheology. Lastly, teleseismic signals from the Yellowknife array at the eastern edge of the profile have Pds-wave conversions correlated with the mantle reflections in the reflection section. The same structural features are observable over several decades of seismic bandwidth. This suggests that teleseismic-converted wave imaging and reflection seismology can be used jointly for high-resolution imaging of the entire lithosphere.

In the 1990s, the German–Chilean–Bolivian ANCORP program conducted reflection, refraction, and teleseismic experiments from the Pacific coast, across the Andes and the Altiplano, to the Eastern Cordillera at about 21°S latitude. The reflection seismic data were acquired to image the deep crust, with relatively large source–receiver offsets (to ±25 km) and widely spaced (~6.3 km), large explosive shots (ANCORP Working Group, 2003). The reflection section (**Figure 5**) and other geophysical data show a number of features that are interpreted as resulting from fluid-controlled processes. Three prominent bands of reflections appear in the section: (1) The Nazca reflector, (2) the Quebrada Blanca Bright Spot, and (3) bands of reflectors associated with the Altiplano low-velocity zone (LVZ). Most of the Nazca reflector, which extends from 40 to 80 km depth and dips at about 20°, is associated with the interplate shear zone atop the subducting Nazca oceanic crust. Receiver-function imaging has identified the oceanic Moho beneath it. The Nazca reflector gains strength and complexity as it deepens. It is interpreted as first a simple lithologic contrast that changes to a zone of dehydration as the subducting oceanic crust enters the amphibole stability field. The free fluids alter local mineralogy and weaken the overlying mantle. The reflections terminate where dehydration is complete, at about 80–90 km depth. Seismicity is low and somewhat diffuse in much of this part of the subducting plate but resumes further downdip, assumed to result from dehydration embrittlement.

The Quebrada Blanca Bright Spot, which dips westward from the active volcanic front of the Andes to the subduction

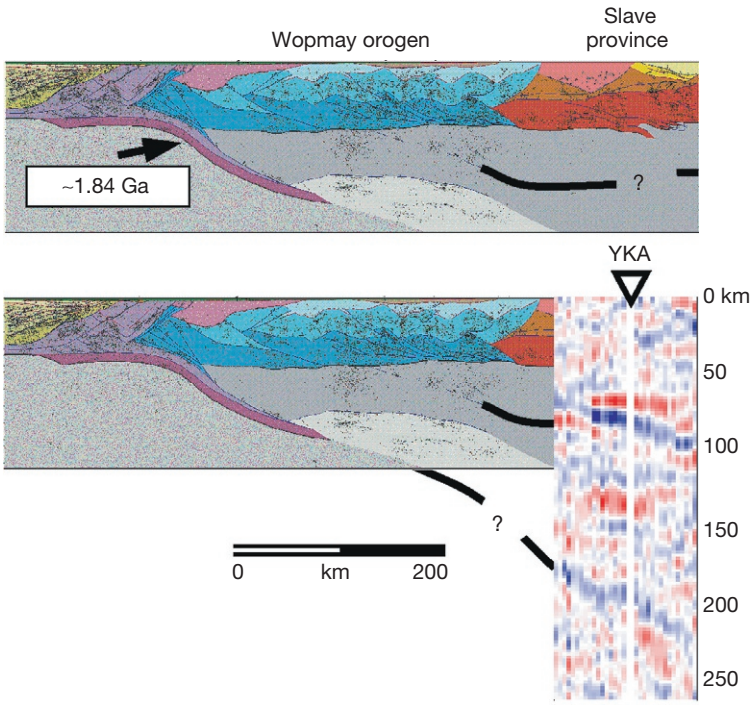

Figure 4 Lithoprobe's time-migrated SNORCLE deep crustal and upper-mantle seismic reflection profile (top and bottom) and receiver functions (bottom) through the Proterozoic Wopmay orogen and Archean Slave Province. The receiver functions made at the Yellowknife (YKA) array show PdS-converted events at the same depths as the vertical incidence reflections (H, and possibly X and L). The profile shows an east-dipping, 1.84-Ga subduction zone in which the subducting oceanic lithosphere appears to be tectonically accreted to the underside of the Wopmay orogen and the Slave Craton. The Moho is relatively flat under the Wopmay orogen with thrust faults soling into the base of the crust. Crustal shortening is accommodated by a succession of west vergent crustal-scale thrusts and duplexes, mantle shortening resulting from subduction with the apparent accretion of some of the subducted oceanic lithosphere to the periphery of the Slave Craton. Reproduced from Cook FA, van der Velden AJ, Hall KW, and Roberts BJ (1999) Frozen subduction in Canada's northwest territories; lithoprobe deep lithospheric reflection profiling of the western Canadian Shield. *Tectonics* 18: 1–24; Bostock MG (1998) Mantle stratigraphy and evolution of the Slave province. *Journal of Geophysical Research* 103: 21193–21200.

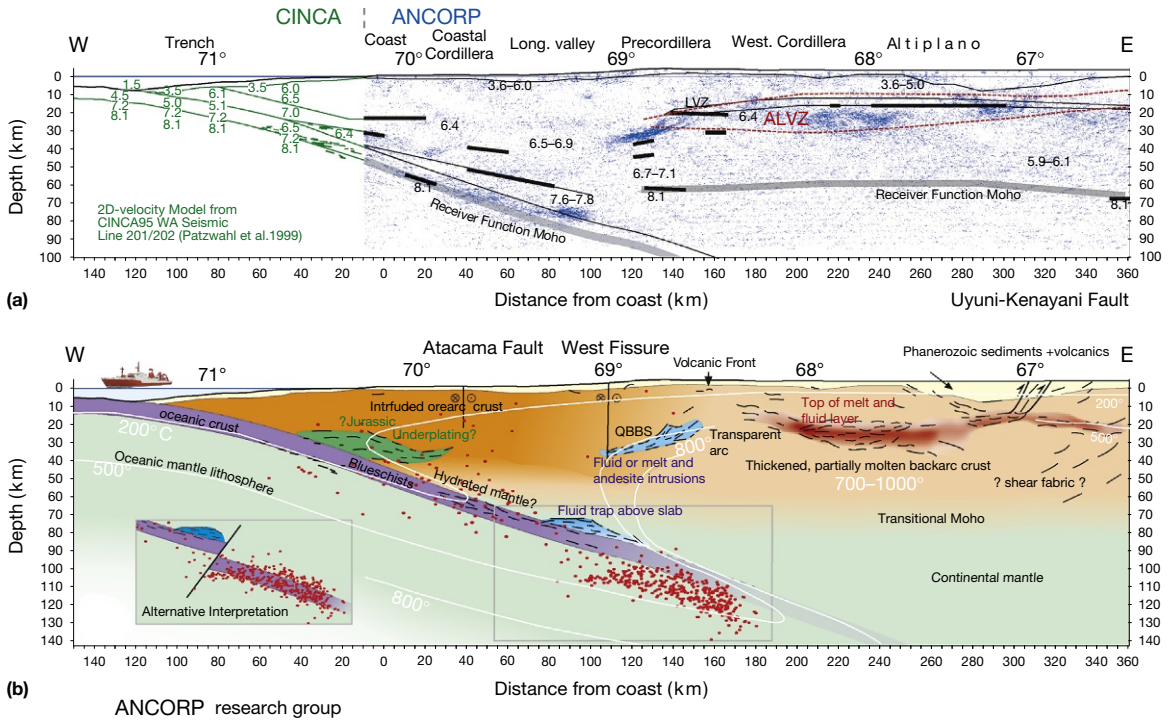

Figure 5 Summary figures showing results from ANCORP (2003) and related experiments across the Andean trench, the Andes, and the Altiplano. (a) The depth-migrated reflection data with seismic refraction and receiver-function results superimposed. The Nazca reflection coincides with the shear zone separating South America from Nazca and is generally aseismic; it is interpreted as a zone of dehydration of the Nazca crust and lithosphere. Seismicity is concentrated deeper and to the east of this reflection and is distributed throughout the upper part of the Nazca Plate as a result of dehydration embrittlement. The Quebrada Blanca Bright Spot (QBBS) reflectors are interpreted as unconnected fluid or possibly melt lenses migrating from the lower crust to the Andean volcanic front. The midcrustal reflectivity beneath the Altiplano is interpreted as the reflection signature from a zone of 20% well-connected partial melt occupying much of the middle crust and corresponding to a zone of low shear-wave velocity identified by receiver functions and a low-conductivity zone from magnetotelluric measurements. (b) An interpretation of all geophysical results including estimated isotherms in the trench region.

zone, shows the strongest amplitude events in the section. These are interpreted as discrete lenses of melt that have migrated from deeper in the subduction system. Interestingly, there is no electrical conductivity anomaly associated with the bright spot, suggesting that the melt lenses are not connected. In contrast, the Altiplano reflectors, although weaker in amplitude, are associated with both a conductivity high and a zone producing large P-to-S conversions in receiver functions. They are interpreted as being from a zone of well-connected pockets of partial melt defining an extensive midcrustal LVZ.

In a surprising application of reflection seismology to physical oceanography, Holbrook et al. (2003) had demonstrated that the temperature–salinity structure of the ocean can be imaged over large areas using CMP reflection surveying (Figure 6). Their data were acquired with a 480 channel, 6 km seismic streamer recording signals from a 140 l air gun array, towed by the *R*/*V* Ewing. Processing the part of the seismic records that had previously been considered water column noise, they identified mixing structures between the cold Labrador Current and the warm North Atlantic Current. This application of reflection seismology to physical oceanography can provide high-resolution details of mixing structures and internal waves and can be used for time-lapse imaging to monitor current changes.

1.15.8 Refraction/Wide-Angle Seismology

There are a number of reviews of methods for wide-angle data analysis: Braile and Smith (1975) demonstrated the amplitude–distance response of 1-D velocity models, stressing the importance of secondary arrivals. Mooney (1983) reviewed methods for calculating synthetic seismograms. Nowack and Braile (1993) reviewed traveltime and amplitude tomography methods in 1-D and 2-D media. Zelt (1999) focused on 2-D traveltime modeling and inversion, as well as model assessment methods. Rawlinson and Sambridge (2003a) presented an overview of traveltime tomography for 2-D and 3-D structure. This set of papers illustrates the evolution in wide-angle data analysis over the past 30 years from an emphasis on forward modeling amplitudes, secondary arrivals, and 1-D and 2-D models to a focus on 2-D and 3-D traveltime automated inversion methods, often using only the first arrivals. This evolution was to a large extent driven by the increase in the typical size of the data set from a few seismograms to hundreds of thousands of traces, combined with a massive increase in computational capability available to researchers. With a small amount of data, the intent was to try to extract as much information as possible. By comparison, the large data volumes today, coupled with a better understanding

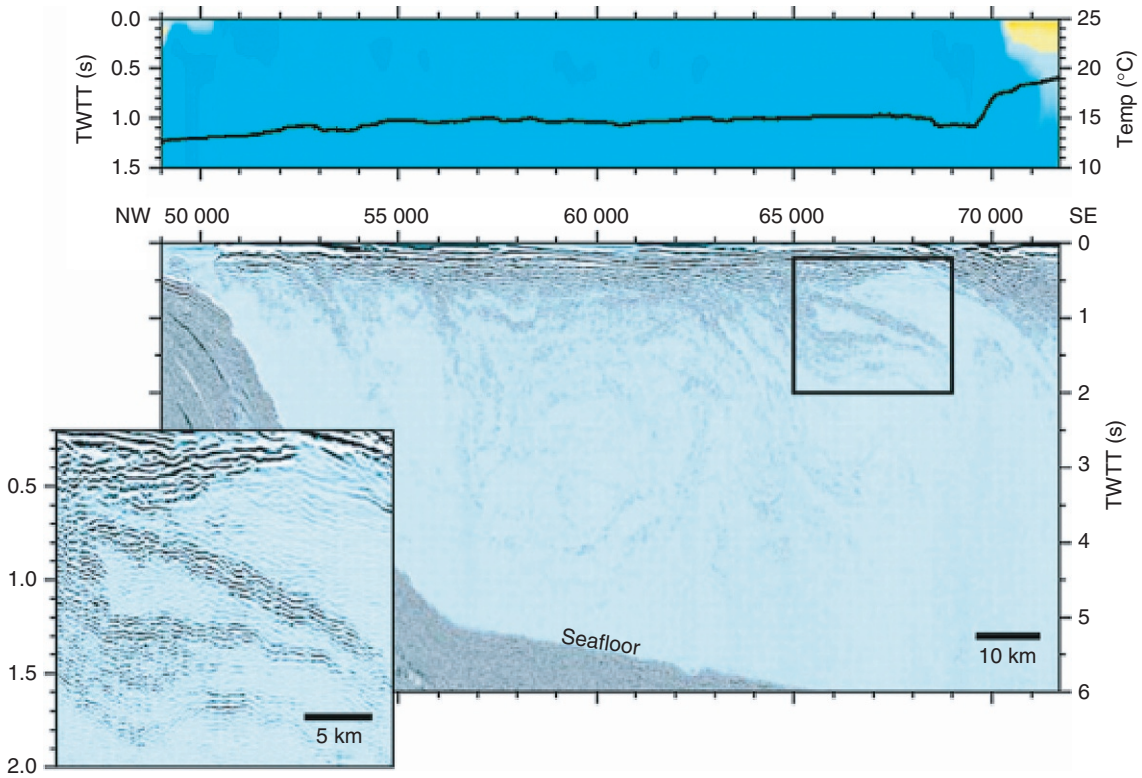

Figure 6 Middle: CMP stacked reflection image of the mixing of the Labrador and North Atlantic Currents made by conventional CMP processing of water column reflections. Previously, events in the water column had generally been considered to be random noise. Holbrook et al. (2003) imaged details of the structure of the mixing of the cold Labrador Current (inset) and the warm North Atlantic Current, with cold water masses descending beneath the warm. Top panel: CMP stacking velocities (color scale: blue, slow minimum 1440 m s^{-1}; red, fast, maximum 1530 m s^{-1}; blue-yellow transition 1503 m s^{-1}) indicating temperature variations in the ocean and intersection of the two currents at CMP 6950. The black line is the sea-surface temperature measured by other means. Middle: from Holbrook WS, Páramo P, Pearse S, and Schmitt RW (2003) Thermohaline fine structure in an oceanographic front from seismic reflection profiling. *Science* 301: 821–824 (http://dx.doi.org/10.1126/science.1085116).

of wave propagation through realistic crustal models, tend to limit wide-angle analysis to the most robust features of the data: traveltimes and often only first arrivals. Recently, there has been a return to using more of the wavefield than traveltimes with 2-D full-waveform inverse methods discussed in Section 1.15.4.

1.15.9 Wide-Angle Seismology Experiments

Wide-angle seismic data have been used to constrain the lithospheric structure of continents, oceans, and their margins for over 40 years. For land experiments, the critical issue is usually the source, in terms of the type, cost, number, and location. Since the seismic waves must propagate ~300 km for crustal and uppermost mantle imaging using first arrivals, a chemical explosive is typically used. The chemicals are normally placed in single or multiple boreholes up to ~100 m deep or at the bottom of moderately deep bodies of water (Jacob, 1975). The objective is to ensure a sufficient cap to avoid releasing energy into the atmosphere and to maximize ground coupling. The total amount of explosives for a single shot is usually in the 50–2000 kg range, depending on the maximum offsets and depths to be investigated (e.g., Kohler and Fuis, 1992). The cost of drilling and explosives usually represents the largest part of the data-acquisition budget, and thus, the total number of sources is often small in comparison with the number of receivers; typically, 5–100 shots are used today. Ideally, the sources should be placed at the ends of the 2-D line and evenly spaced within, unless more resolution is required along a portion of the line. 3-D crustal wide-angle land surveys are relatively rare since the number of sources required to achieve a spatial resolution comparable to a 2-D survey is very high. Typically, the number of sources used in a 3-D land survey means that only large-scale crustal structure will be resolved, and often, 3-D data are a secondary component of an otherwise 2-D survey involving one or more lines (e.g., Kanasewich and Chiu, 1985; Zelt et al., 2006b).

For wide-angle land experiments, typically 100 to >1000 recorders are used, each one being a compact autonomous unit consisting of a digital acquisition system, an accurate clock, and a vertical-component geophone; three-component instruments are often embedded in surveys, but complete three-component surveys are still relatively rare. The sample rate is typically 2–16 ms and lightweight high-frequency geophones with a natural frequency of 4.5–40 Hz are used. Discrete recording windows can be programmed to capture land shots, or continuous recording of up to a few days can capture air gun shots in an onshore–offshore experiment (see later text). The recorders are typically programmed at a central field location and returned for download and clock check after recovery. One important difference between an active geophone deployment and a passive geophone deployment is that many instruments are deployed in 1 or 2 days and are left in the field for only a day to a week. As a result, there is less time available to ensure ideal geophone coupling, and the typical 100 m to 1 km receiver spacing along profiles means it is not possible to always choose ideal site conditions. Thus, modern active experiments rely on a large data volume with little or no site characterization, with a data loss of 5–10% expected due to instrument malfunction, deployer error, site noise, and theft in populated areas.

The experimental setup for a marine wide-angle survey is very different from a land survey. Air gun arrays are the most common source, often the same source being used for simultaneous acquisition of multichannel reflection data by towing a streamer from the same ship. Sometimes, the air gun array will be tuned to a lower center frequency when deep crustal wide-angle data are being collected given that longer source–receiver offsets are sought. Typically 10–100 ocean-bottom seismometers (OBSs) or hydrophones (OBHs) are used to record marine wide-angle data, the former usually consisting of three components and one hydrophone. They may be deployed from the shooting ship or a second ship and are normally programmed to record continuously for a few days and are then recovered by the same ship using a timed release or acoustic signal. The internal workings of an OBS or OBH are similar to a land recorder with respect to memory and an accurate clock. Since the sound source can cycle at a rate of 20 s or less (a common shooting rate for reflection data), previous shot noise generated within the water column can be a major noise source for wide-angle marine data. As a result, a longer shot interval of 60–120 s is used to record wide-angle data only. If both wide-angle and reflection data are sought, either the lines will be collected twice using the short and long shot intervals or a compromise shot interval of 30–45 s is used.

A combined vertical to wide-angle experiment known as an onshore–offshore survey has become quite popular in the past ~15 years. Land stations record marine shots and/or ocean-bottom receivers record land shots (e.g., BABEL Working Group, 1993; Henstock et al., 1997; Morgan et al., 2000; Park et al., 2007). As a result, there is continuous data coverage across a land–water boundary, ideal for studying continental margins. Coincident but independent near-vertical reflection and wide-angle experiments are quite common (e.g., Mooney and Brocher, 1987), but in some modern experiments, both types of data are acquired simultaneously using densely spaced shots and receivers with sufficient offset that deep-penetrating first-arrival refractions are recorded (e.g., Fuis et al., 2001; Lafond and Levander, 1995; Levander et al., 1994). These types of data allow both conventional reflection and wide-angle analysis techniques and wide-angle migration and waveform inversion (both discussed later). Similar experiments, known as deep seismic soundings (DSSs), were once common in Russia and India, but they usually did not use sufficient offsets to observe upper-mantle refractions, Pn (e.g., Kaila and Krishna, 1992). Wide-angle experiments with very long source–receiver offsets (>1000 km) have been used to image deep subcrustal lithospheric and asthenospheric structure (e.g., Gorman et al., 2002), particularly in the former Soviet Union in which peaceful nuclear explosions were sometimes available as sources (e.g., Morozova et al., 1999; Neves et al., 1996; Thybo and Perchuc, 1997).

For upper-crustal and near-surface wide-angle studies, the experimental parameters mentioned previously for whole-crustal studies can be appropriately scaled, although the number of sources and receivers will remain roughly the same. The size of explosive near-surface sources ranges from tenths to tens of kilograms of explosives, and there are many viable nonexplosive sources, such as hammers, weight drops, rifles,

shotguns, and minivibes (e.g., Hole et al., 2006; Hughes et al., 1998; Jarchow et al., 1994; Lanz et al., 1998; Zelt et al., 2006a).

The modeling and inversion algorithms discussed later can be used to help design the optimum survey geometry given particular instrument resources and anticipated geologic structures (e.g., Peirce and Day, 2002).

1.15.10 Data Processing

A major difference between conventional analyses of wide-angle data and reflection data is the use of a model-based approach versus a signal-processing approach for the latter. The reason for this is because it is possible to convert reflection data into a high-resolution, geologically interpretable form, ideally a representation of the primary reflectivity of the Earth. Much of this analysis is only weakly dependent on the velocity structure of the crust. However, for wide-angle data, the primary objective is to determine the velocity structure of the crust and uppermost mantle. Therefore, the analysis of wide-angle data typically includes only a minimal amount of data processing to 'clean up' the data to make it easier to pick arrival times from the seismograms. Band-pass filtering, velocity (frequency–wave number) filtering, trace summing, and deconvolution are sometimes used to remove incoherent and coherent noise and reduce complications from a ringy source, multiple reflections, or previous shot noise, particularly in marine data (Christeson et al., 1999; Nakamura et al., 1987). Except for 1-D modeling of wide-angle data, corrections for elevation and low surface velocities are neglected as they depend on the unknown velocity structure. Instead, most 2-D and 3-D modeling algorithms for wide-angle data allow the known surface topography and bathymetry to be incorporated into the model. If a 1-D velocity model is sought, either as a final result or as a starting model for subsequent 2-D or 3-D modeling, data processing/inversion techniques exist, such as tau-p inversion (e.g., Clayton and McMechan, 1981; Gorman and Clowes, 1999). In some cases, particularly with very laterally heterogeneous near-surface structure, phase identification and arrival picking may be difficult, and a processing technique such as wave equation datuming may prove effective (Hill and Wuenschel, 1985; Larkin and Levander, 1996). For marine data, applying corrections for rugged seafloor topography may be necessary (e.g., Purdy, 1982; Spudich and Orcutt, 1980).

Picking wide-angle arrival times is normally done from shot or receiver gathers, exploiting the lateral coherence of closely spaced traces. Fully automated picking routines are usually not possible because of noise, lateral waveform changes, and onsets of later arrivals buried in the seismic coda. Interactive software is used to pick arrivals 'manually' by eye for each trace, or a representative subset of traces are picked and the intervening picks are determined automatically using a cross correlation scheme (Zelt, 1999). Initially, only the most obvious arrivals are picked, typically the first arrivals. These initial arrivals are used to develop a preliminary model to help identify additional arrivals by overlaying predicted times on the data and then using the new set of picks to further develop the model in a bootstrap fashion. Interpolating traveltime picks across significant gaps will provide an incorrect sense of model constraint and is to be avoided (Zelt, 1999).

Assigning prior uncertainties to the arrival picks avoids over- or underfitting the data and allows the appropriate up- and downweighting of less noisy and more noisy data, respectively, when an inverse method is used (Zelt, 1999). Uncertainties are often assigned qualitatively by inspection, taking into account the data's signal-to-noise ratio and frequency content. Zelt and Forsyth (1994) used an automated scheme involving an empirical relationship between signal-to-noise ratio and pick uncertainty. Another guideline for assigning pick uncertainties is the time differences of reciprocal pairs (Zelt et al., 2006a) or where two profiles intersect (Park et al., 2007). Toomey et al. (1994) estimated picking uncertainties as part of an automated picking routine.

1.15.11 Model Dimension

Up until about 1980, wide-angle data were generally modeled using a laterally homogeneous (1-D) representation of the Earth structure (Mooney, 1983). This simplification allows for a number of efficient forward modeling and linear inversion techniques of the traveltimes and wavefield for velocity as a function of depth, such as the reflectivity method, Herglotz–Wiechert inversion, and tau-p inversion (Aki and Richards, 2002, pp. 413–429; Clayton and McMechan, 1981; Fuchs and Muller, 1971). These inversion techniques assume a monotonically increasing velocity–depth model, which in most tectonic settings is reasonable, but in some cases may be too restrictive, such as in high heat flow regions (Smith et al., 1975; Wenzel and Sandmeier, 1992). If LVZs are involved, wide-angle reflections from the top and bottom of the LVZ can be used to constrain them (e.g., Sain and Kaila, 1996). The 1-D 'reflectivity' method has been very popular because of its ability to provide elastic full-wavefield seismograms. The reflectivity method is also used where the velocity model is weakly 2-D so that a 1-D average for amplitude calculations is acceptable given that typically only the large-scale amplitude trends are modeled (e.g., Benz et al., 1990; Zelt and White, 1995). 1-D modeling can also be used to construct a starting model for 2-D or 3-D analysis. In this case, the 1-D assumption is made for each shot or receiver gather, and the resulting velocity–depth profiles are interpolated to form an initial 2-D model. Alternatively, the traveltime picks from all shots and receivers can be used to derive the best-fitting 1-D model, which is then used as a starting model for 2-D or 3-D inversion (e.g., Zelt and Barton, 1998).

In the late 1970s, asymptotic (i.e., infinite-frequency) ray theory for laterally heterogeneous (2-D) media was adopted for interpretation of wide-angle data, including the calculation of synthetic seismograms (Cerveny et al., 1977; McMechan and Mooney, 1980; Mooney, 1983). This was a significant step forward because it meant that Earth models of arbitrary lateral complexity could be considered, providing the tenants of ray theory were honored, that is, the velocity field varies slowly with respect to the seismic wavelengths involved. Sharp velocity changes are modeled using a velocity discontinuity, that is, a layer boundary, and the application of Snell's law. As a result, 2-D ray theory models are typically composed of one or a few

layers, bounded by smoothly varying interfaces, within which the velocity varies smoothly.

In the 1990s, acquisition of 3-D crustal wide-angle data became quite common, not only particularly in the oceans as 3-D marine surveys have simpler logistics, shallower targets requiring smaller offsets, and hence lower costs (e.g., Toomey et al., 1994; Zelt and Barton, 1998) but also on land (e.g., Zelt et al., 1996) and crossing ocean–continent boundaries in onshore–offshore experiments (Hole et al., 2000a; Morgan et al., 2000). The cost of most 3-D surveys is high, especially if the spatial resolution is to be comparable to a state-of-the-art 2-D survey, and so they are used when 2-D sampling of the target will be insufficient to address the research objectives. Sometimes, relatively sparse 3-D crustal data sets are acquired as a result of a primarily 2-D survey that includes some broadside recordings, that is, shots from one profile recorded by receivers along another profile. The advantage of these types of surveys is that little or no compromise on the quality of the 2-D imaging is necessary but the additional sparse 3-D coverage may reveal structures not present in the 2-D models (e.g., Zelt et al., 2006b).

For a 2-D survey in which the shot and receiver locations deviate significantly from a straight line, it may be necessary to consider 2.5-D modeling, that is, using a 3-D model and 3-D ray tracing and the known topographic and bathymetric surfaces, but keeping the velocity model homogeneous in a direction perpendicular to the main trend of the profile (e.g., Van Avendonk et al., 2004). Given the resolution of most wide-angle velocity models, the degree of profile 'crookedness' must be substantial to warrant 2.5-D modeling (Zelt and Zelt, 1998).

1.15.12 Forward Modeling

The late 1970s saw the introduction of various methods for calculating ray paths and traveltimes in laterally heterogeneous media (2-D and 3-D), thereby establishing the basis of wide-angle data analysis used today. Two end-member approaches to ray tracing were put forward: numerical and analytic. In the former case, the velocity field is specified by a regular (e.g., McMechan and Mooney, 1980) or irregular (e.g., Zelt and Ellis, 1988) grid of nodes, together with a scheme for interpolation between nodes, and a ray is traced by specifying a takeoff angle from a point source and solving a set of ordinary differential equations, the ray-tracing equations (Cerveny et al., 1977). In the analytic case, the velocity field can be specified by a regular (e.g., Chapman and Drummond, 1982; Rawlinson et al., 2001; White, 1989) or irregular (e.g., Spence et al., 1984) grid of nodes, but with a form of interpolation, typically linear, such that the ray paths can be calculated analytically. In practice, the analytic and numeric techniques are often about equally efficient if the analytic method uses a fine mesh of nodes to represent a sufficiently smooth velocity field as dictated by ray theory and if the numeric scheme adjusts the step length according to the velocity gradients (Zelt and Ellis, 1988).

For an arbitrary 2-D velocity model, a nontrivial consideration is the determination of ray takeoff angle from the source such that an arbitrary receiver point is reached or such that a particular layer or interface in the model is sampled. In early algorithms, it was left to the user to determine the necessary takeoff angles through trial-and-error shooting of fans of rays (e.g., Spence et al., 1984). Today, most 2-D ray-tracing codes offer an automatic determination of takeoff angles using a shooting approach and a bisection algorithm to sufficiently refine the takeoff angles so that the receiver points are hit (e.g., Zelt and Smith, 1992). The robustness of the shooting method is critical because the data from receivers for which it is not possible to find rays cannot be used in the forward or inverse modeling. Also, it is important to be sure that an inability to find rays is because of the model, for example, a shadow zone, as opposed to a shortcoming of the shooting algorithm.

To avoid the limitations of shooting, particularly for 3-D models, ray-bending methods were developed (Julian and Gubbins, 1977; Um and Thurber, 1987). In this approach, a ray path connecting a source and receiver is estimated, normally using a 1-D reference model, and the ray path is iteratively updated using Fermat's principle until the minimum-time path is determined. In practice, shooting methods are more efficient and sufficiently robust for 2-D models, whereas bending methods are favored for 3-D models. Zhao et al. (1997) and Chiu et al. (1986) applied bending methods to the inversion of 2-D and 3-D wide-angle data.

In the late 1980s, a new forward modeling approach was introduced in which first-arrival traveltimes are calculated on a fine grid using a finite-difference solution of the eikonal equation (Podvin and Lecomte, 1991; Van Trier and Symes, 1991; Vidale, 1988, 1990). Ray paths are obtained in a second step by following the gradient of the traveltime field. These methods have become very popular and are collectively known as wavefront-tracking methods (also known as eikonal solvers). Reflection ray paths can be calculated in a two-step procedure by calculating downgoing and upgoing wavefronts (Hole and Zelt, 1995). Hole and Zelt (1995) also presented a modification to the Vidale approach, which otherwise breaks down for velocity contrasts of more than ~40%. The advantage of finite-difference methods is that they find the fastest ray between any two points, including the diffracted path in the case of a geometric shadow zone, and they can be very efficient, especially for 3-D models. The disadvantages are they are computationally cumbersome for calculating later arrivals, and they can be inaccurate and/or computationally intensive for high-velocity contrast media. Another potential problem is that the calculated first-arrival time may correspond to a very low-energy arrival, something that may not be recognized in real data. Another type of wavefront-tracking scheme that solves the eikonal equation is the fast marching method, which is computationally efficient and unconditionally stable (Popovici and Sethian, 2002; Rawlinson and Sambridge, 2004; Sethian and Popovici, 1999). Eaton (1993) developed a finite-difference method for anisotropic media.

Nakanishi and Yamaguchi (1986) and Moser (1991) introduced the shortest-path ray-tracing method based on Fermat's principle, which uses a fine network of nodes and graph theory. It is capable of handling arbitrarily heterogeneous media and calculating first arrivals, reflections, and multiples easily. Its advantages over finite-difference methods are robustness and the grid does not have to be rectangular or regular. However, its memory and computation requirements are greater.

Van Avendonk et al. (1998) and Van Avendonk et al. (2001) developed a hybrid of the shortest-path and ray-bending methods building on the work of Moser (1991) and Moser et al. (1992). The hybrid method uses the shortest-path algorithm to find an initial ray path that is close to the minimum-traveltime path and then refines it using a bending method. The result is an efficient and robust algorithm to calculate accurate traveltimes and ray paths for refractions and reflections in 2-D and 3-D media.

1.15.13 Traveltime Inversion and Tomography: Theory and Practical Issues

Today, 2-D and 3-D traveltime inversion and tomography are the central analysis methods applied to crustal wide-angle data. In this section, we present an overview of the mathematical theory and practical considerations of the algorithms in use today. The distinction between inversion and tomography is not well defined in the seismology community. The latter usually implies a uniform, fine-grid model parameterization, in which a smooth model is sought (e.g., Toomey et al., 1994; Van Avendonk et al., 1998; Zelt and Barton, 1998). Any departure from this approach is usually referred to as traveltime inversion (e.g., Rawlinson et al., 2001; Spence et al., 1985; Zelt and Smith, 1992), although the distinction is an arbitrary one, as the mathematical description in the succeeding text shows. Here, we caution the reader that some notation used in reflection seismology is also customarily used in wide-angle seismology, but with different meanings. In this section, L is the ray path (as opposed to wave operator), and G is the matrix of Fréchet derivatives, rather than a Green's function.

The traveltime t between a source and receiver along a ray path L is given in integral form for a continuous or piecewise continuous velocity field $v(\mathbf{r})$ as

$$t = \int_L \frac{\mathrm{d}l}{v(r)} \qquad [43]$$

where $\mathbf{r}$ is the position vector in 2-D or 3-D media. Finding $v(\mathbf{r})$ is a nonlinear inverse problem given the relationship between the measured data (traveltimes) and the unknown model parameters (the velocity field). However, by transforming variables to use slowness $s(\mathbf{r})$, the reciprocal of velocity, instead of velocity as the unknown, a linear inversion problem is created:

$$t = \int_L s(\mathrm{r})\mathrm{d}l \qquad [44]$$

However, the ray path L is also dependent on the velocity (or slowness) model (Figure 2), thus making the inverse problem nonlinear regardless of what form of model variable or parameterization is used.

In global seismology, a 1-D (radially symmetrical) Earth model is often used to predict the ray paths given the relatively small velocity heterogeneities in the mantle, thereby converting the inverse problem into a linear one (e.g., Grand, 1994). In crustal seismology, there is no concept of a reference model that is sufficiently accurate to predict the ray paths in advance given the relatively large velocity heterogeneities that are typically encountered in the crust and uppermost mantle (Figure 7). This means the wide-angle traveltime inverse problem is always treated as nonlinear, in which both the velocity field and ray paths are treated as unknowns to be solved for. This also means the model can be parameterized any number of ways using velocity or slowness and nodes, cells, or splines, since the problem's nonlinearity must be dealt with irregardless of the parameterization. Most often, this means a linearized gradient approach is applied in which a starting model must be provided and both the model and ray paths are updated over a series of iterations with the hope that there will be convergence to an acceptable model.

For virtually all traveltime problems, the model is discretized using cells, nodes, splines, or other interpolating functions; in the latter two cases, the discrete model parameters are the coefficients of the interpolating functions. In the simplest formulation of the tomography problem, the model is parameterized using constant-slowness cells, in which case the equation for the ith data becomes

$$t_i = \sum_j l_{ij} s_j \qquad [45]$$

where l_{ij} is the length of the ith ray in the jth model cell and s_j is the slowness in the jth cell. In vector–matrix form, this is

$$t_i = L\mathrm{s} \qquad [46]$$

Applying a Taylor series expansion to this equation, assuming the ray paths are independent of slowness, and keeping only the linear term yields the perturbation equation

$$\delta t = \mathrm{G}\delta\mathrm{s} \qquad [47]$$

where δt is the data residual or misfit vector equal to the difference between the observed traveltimes and those predicted by a prior model and $\delta\mathrm{s}$ is the difference between the unknown model and the prior model; the unknown model is also called the estimated model. The partial derivative matrix, $\mathbf{G}$, contains the elements $\mathrm{g}_{ij} = \partial t_i / \partial s_j$, and for the constant-slowness cell parameterization, $\mathrm{g}_{ij} = l_{ij}$ or $\mathrm{G} = \mathrm{L}$. In the general case, the elements of the partial derivative matrix are $\mathrm{g}_{ij} = \delta t_i / \delta m_j$ where m_j is the jth model parameter, which could be the velocity at a node or the coefficient of an interpolating function, or the position of an interface within the velocity model (e.g., Zelt and Smith, 1992). In the general case, the perturbation equation becomes

$$\delta t = \mathrm{G}\delta\mathrm{m} \qquad [48]$$

The elements of the partial derivative matrix $\mathbf{G}$ are usually calculated analytically, to avoid the potential inaccuracy of numerical differencing and the extra computation needed to trace additional rays. The approximations involved in the analytic partial derivatives, for example, the stationary ray-path assumption, are typically not a problem since the resultant gradient direction in model space can be improved with each iteration of the nonlinear process.

The perturbation equation is not solved directly because the unknown model parameters are typically under- or mix-determined (Menke, 1989), depending on the model parameterization; with relatively few model parameters, it is possible for the problem to be overdetermined, but even in this case, the perturbation equation is not solved directly because it is wise to

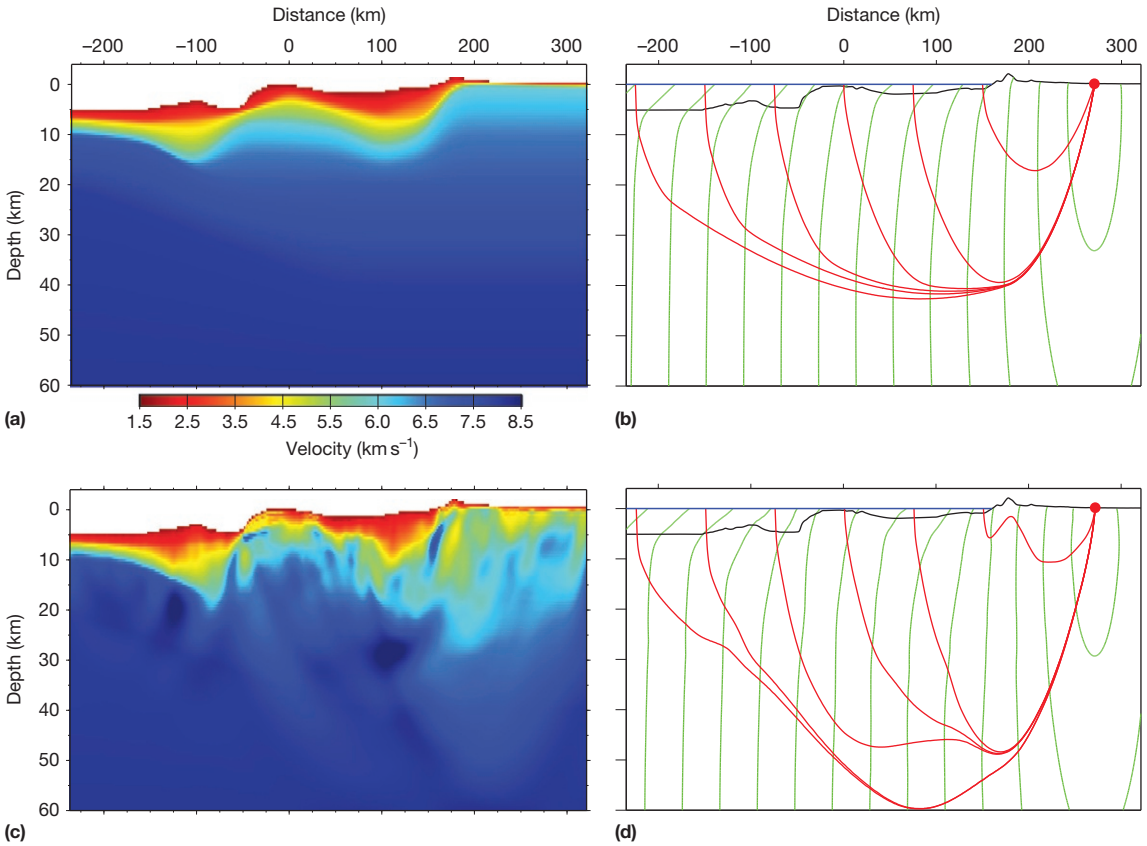

Figure 7 Example from an onshore–offshore study of the Venezuelan margin at 67.5 W (Zelt et al., 2004) to illustrate one aspect of nonlinearity in the inversion of wide-angle data. (a) Starting velocity model that provides an rms traveltime residual with respect to the picked times of ~1.0 s. (b) First-arrival ray paths between shots 75 km apart and receiver ~100 km inland (red) and isochrones (green) for the model in (a). Black line is bathymetry/topography; blue line is sea surface. (c) Final velocity model that provides an rms traveltime residual with respect to the picked times of about ~0.1 s. (d) First-arrival ray paths between the same shots and receiver as in (b) for the model in (c); details the same as in (b). Note the considerable difference between the ray paths in the two models as a result of the heterogeneity in the final model.

constrain the magnitude of the model perturbation to avoid violating the linearization assumption. Thus, regardless of whether the problem is underdetermined or overdetermined, model constraints, in addition to the observed data, are included to stabilize the solution. Since all observed data contain noise, it makes no sense to overfit noisy data, so additional model constraints are required to select one model from an infinite number that will statistically predict the observed data at the equivalent desired misfit according to the estimated noise level. This issue points out the nonuniqueness of all inverse problems involving real data, regardless of whether the system of equations is overdetermined or underdetermined.

The additional model constraint is called regularization (e.g., Scales et al., 1990), and in addition to stabilizing a solution, it is an effective way of steering the solution toward models with desirable predefined characteristics. The regularization is most often in the form of the zero-, first-, or second-order spatial derivatives of the estimated model parameters, or their perturbation from a reference model. This is because it is usually considered desirable to seek an estimated model that is as close as possible to a prior reference model and/or a model that has minimum structure as measured by its spatial derivatives in keeping with Occam's principle (e.g., Constable et al., 1987; Menke, 1989).

The most common forms of regularization in traveltime problems are the minimization of the model's perturbation from a prior model and the minimization of the second-order spatial derivative of either the whole model or its perturbation from a prior model. These are called the smallest and smoothest models, respectively. Any combination of model constraints may be included as a part of the regularization to form the objective function, $\Phi(m)$, where $\mathbf{m}$ is the vector containing the estimated model parameters. The objective function usually measures the square of the data residual vector and the square of the model constraints so that minimizing it leads to a linear system of equations that is amenable to efficient algorithms for their exact or approximate solution. One example of a practical objective function for the traveltime problem is

$$\Phi(\mathbf{m}) = \delta\mathbf{t}^{\mathrm{T}}\mathbf{C}_{\mathrm{d}}^{-1}\delta\mathbf{t} + \lambda\left\{\beta\left[\alpha\left(\mathbf{v}^{\mathrm{T}}\mathbf{W}_{\mathrm{h}}^{\mathrm{T}}\mathbf{W}_{\mathrm{h}}\mathbf{v} + s_Z\mathbf{v}^{\mathrm{T}}\mathbf{W}_{\mathrm{V}}^{\mathrm{T}}\mathbf{W}_{\mathrm{V}}\mathbf{v}\right)\right.\right.$$
$$\left. + (1-\alpha)\Delta\mathbf{v}^{\mathrm{T}}\mathbf{W}_{\mathrm{P}}^{\mathrm{T}}\mathbf{W}_{\mathrm{P}}\Delta\mathbf{v}\right] + (1-\beta)\left[\mathbf{z}^{\mathrm{T}}\mathbf{W}_{\mathrm{P}}^{\mathrm{T}}\mathbf{W}_{\mathrm{P}}\Delta\mathbf{v}\right]$$
$$\left. + (1-\beta)\left[\mathbf{z}^{\mathrm{T}}\mathbf{W}_{Z}^{\mathrm{T}}\mathbf{W}_{Z}\mathbf{z}\right]\right\} \qquad [49]$$

where $\mathbf{m} = \mathbf{v} + \mathbf{z}$ and $\mathbf{v}$ and $\mathbf{z}$ are vectors containing the estimated model parameters defining the velocity (or slowness)

field and the depth of interfaces; Δv is the velocity perturbation vector equal to $\mathbf{v}-\mathbf{v}_0$, and $\mathbf{v}_0$ is the reference velocity model vector. $\mathbf{C}_d$ is the data covariance matrix containing the estimated pick uncertainties, providing the appropriate upweighting and downweighting of the low- and high-noise data, respectively. $\mathbf{W}_h$ and $\mathbf{W}_v$ are the horizontal and vertical roughness matrices containing the second-order spatial finite-difference operators that measure the roughness of the velocity field in the horizontal and vertical directions, respectively; $\mathbf{W}_p$ is the velocity perturbation weighting matrix, which is a diagonal matrix containing the weights applied to the perturbation between each estimated and reference velocity model parameter; $\mathbf{W}_z$ is the interface roughness matrix containing the first-order spatial finite-difference operators that measure the variation of the interfaces.

When applying derivative operators to the velocity field, it is common to use different operators to measure the horizontal and vertical structure and weight these differently, since one expects the Earth to contain more structure vertically than horizontally. Any or all of these operators may be normalized by the reference model values so that relative quantities are penalized as opposed to absolute values (e.g., Toomey et al., 1994). In addition, the operators can be weighted according to their spatial position, for example, penalize structure more in the deep portion of the model versus the shallow portion since with wide-angle data, one would generally expect decreasing resolution with depth. The relative weight of each term in the objective function is determined by the free parameters λ, β, α, and s_z. The inversion is stabilized by systematic reduction of the overall amount of regularization, controlled by λ, allowing long-wavelength structure in the initial iterations and progressively finer model structure in later iterations (e.g., Zelt and Barton, 1998).

Minimizing the objective function with respect to the unknown model parameters ($\mathbf{v}$ and $\mathbf{z}$) leads to a system of linear equations that may be very large, depending on the number of data and model parameters. By today's standards, a small problem would involve on the order of 10^3, or less, data and model parameters, and a large problem would involve 10^5, or more, data and model parameters; the former will likely be 2-D problems, and the latter will be 3-D.

The example objective function can be simplified or slightly modified to correspond to those used in most of the popular traveltime inversion and tomography algorithms. For example, the Zelt and Smith (1992) inverse method includes only perturbation constraint on the velocity and interface parameters with respect to the model from the previous iteration; this is the classical damped least-squares solution (Menke, 1989). The Zelt and Barton (1998) regularized tomographic method includes only smoothness constraints on the velocity field. Thus, these two algorithms can be viewed as end-members of the same regularized inverse approach we have presented, and most algorithms in use today fall somewhere in between. The main differences between the algorithms discussed in the next section lie not just in the details of the objective function, but more so in the form of model parameterization, forward calculation, and the types of arrivals considered.

If the linear system is large, it will typically be very sparse with 99.9% or more zero elements. In this case, it can be solved efficiently using an iterative, sparse linear-system solver, for example, the LSQR variant of the conjugate gradient algorithm (Nolet, 1987; Paige and Saunders, 1982). Another effective approach is the subspace method, particularly for mixed-parameter problems (Rawlinson et al., 2001). If the linear system is relatively small, it can be solved directly using standard matrix inversion routines, such as LU decomposition (Press et al., 1992).

Including both velocity and interface parameters in a single inversion scheme makes the problem significantly more complicated. There will be more model nonuniqueness because of trade-offs between the two parameter types, and more subjective prior information will be required in order to deal with the increased ambiguity (**Figure 8**). Also, more testing will be required to ensure that the trade-offs are fully understood.

When regularization is applied to the estimated model parameters or their perturbation from a fixed reference model, it is called a 'jumping' strategy (the former strategy is a special case of the latter in which the reference model is zero); when it is applied to the perturbation between the estimated model and the model from the previous iteration, it is called 'creeping.' The rationale for jumping is that the final model will be less dependent on the starting model since the model constraints are relative to a fixed model at each iteration and not an intermediate model encountered along the path in model space between the starting and final models. Creeping is used when the starting model and intermediate models are deemed to be significant and there is a desire for the final model to represent the end of a series of related models. The jumping strategy is more objective, whereas creeping allows the solution to be steered more easily to a desired result.

Almost all traveltime inversion and tomography algorithms today employ a jumping strategy (Shaw and Orcutt, 1985). The Zelt and Smith (1992) algorithm uses creeping to achieve what has been described as a method for automated forward modeling.

Assuming uncorrelated, Gaussian picking errors and a model parameterization that does not limit the degree to which the observed data can be matched by the predicted data, a final model should be chosen that provides a normalized misfit, χ^2 (Bevington, 1969), of one:

$$\chi^2 = \frac{1}{N}\left[\delta \mathbf{t}^{\mathrm{T}} \mathbf{C}_{\mathrm{d}}^{-1} \delta \mathbf{t}\right] \qquad [50]$$

where N is the number of data. A model that provides a χ^2 value less than 1 means the observed data are being overfit, and therefore, the noise in the data is also being fit. Although the χ^2 criterion is a good rule of thumb, there are several reasons why it should not always be followed strictly. First, traveltime picking errors of wide-angle data are likely never uncorrelated because each trace is usually picked from a shot or receiver gather by considering the correlation of waveforms adjacent to the trace being picked, either by eye or by using a cross correlation picking algorithm (Zelt, 1999). Second, for relatively sparse wide-angle data from a region with strong lateral heterogeneities, it may be necessary to use so many independent model parameters in order to achieve $\chi^2 = 1$ such that the constraint on some parameters is unacceptably small, in which case fewer parameters and a χ^2 value greater than one may be preferable (Zelt, 1999). An inability to reach $\chi^2 = 1$

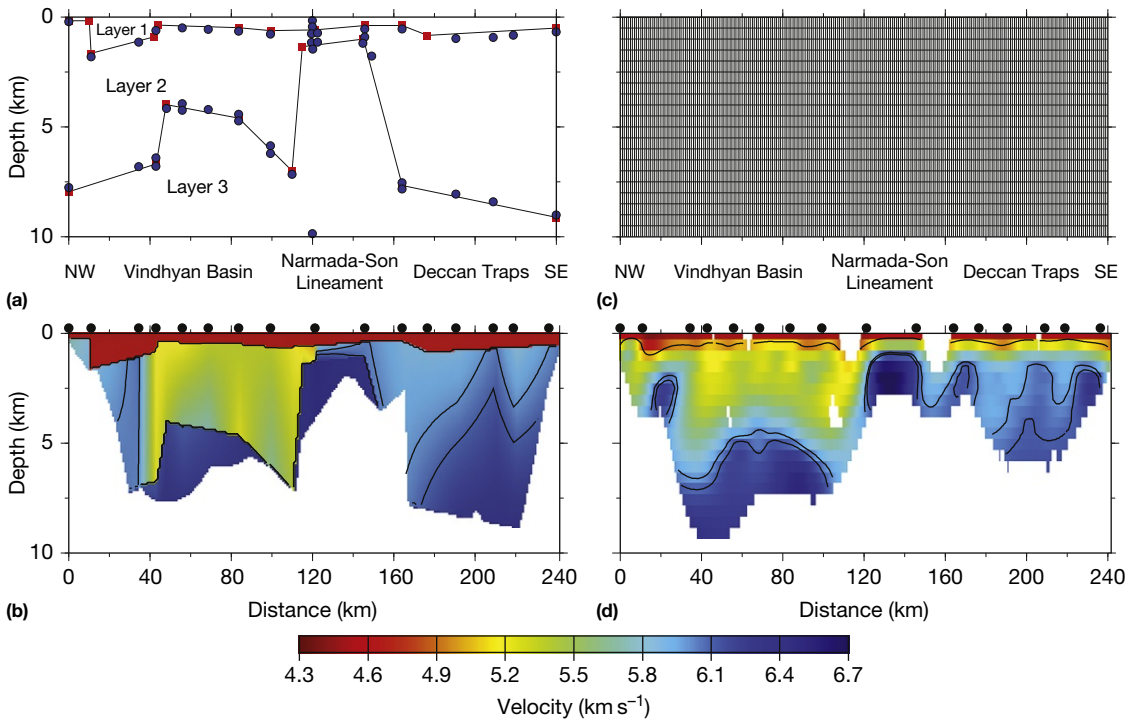

Figure 8 Example from Central India across the Narmada–Son lineament of applying two different traveltime inversion algorithms to the same wide-angle data (Zelt et al., 2003). (a) Model parameterization using the Zelt and Smith (1992) algorithm; there are 43 velocity nodes (blue dots) and 21 interface nodes (red squares). (b) Velocity model corresponding to parameterization in (a). (c) Model parameterization using the Zelt and Barton (1998) algorithm; there are 7018 slowness cells. (d) Velocity model corresponding to parameterization in (c). Only those portions of the models sampled by ray paths are shown. Isovelocity contours of 5.0 km s^{-1} (black) and 6.0 and 6.1 km s^{-1} (white) indicated. Shot point locations (black dots) and geologic features labeled above the models.

may be because of picking inconsistencies of reciprocal pairs, or where two profiles intersect; in either case, the inconsistencies should either be corrected or be used as the basis for assigning the pick uncertainties in the first place (e.g., Park et al., 2007; Zelt et al., 2006a).

Objective functions using L_p-norms with $p < 2$ may be desirable because the solutions will be less influenced by outliers. Iteratively reweighted least squares (IRLS) is a method for approximating the use of an L_p-norm (Scales et al., 1988). Since it is an iterative approach, it can be incorporated into a nonlinear traveltime algorithm with virtually no additional computation because there is already a need for an iterative solution. IRLS is not commonly used in wide-angle traveltime inversion probably because outliers are unlikely when picking traces within gathers, as opposed to individual seismograms as in earthquake seismology.

Global optimization (GO) methods are well suited to very nonlinear problems since their dependence on the starting model is small or none at all (Sen and Stoffa, 1995). However, they are computationally demanding and limited to problems in which the forward calculation is very quick and there are relatively few model parameters. This means GO is not commonly applied to fine-grid traveltime inversion problems, except to find a suitable starting model for a linearized gradient method. Pullammanappallil and Louie (1994) and Boschetti et al. (1996) applied GO schemes to small 2-D traveltime problems.

1.15.14 Traveltime Inversion and Tomography: Algorithms

Up until the 1990s, 2-D ray-tracing and traveltime forward modeling through trial-and-error means, often supplemented by comparisons with synthetic seismograms, was the most common method for the analysis of wide-angle data. Popular algorithms were those of Cerveny et al. (1977) and McMechan and Mooney (1980). Trial-and-error forward modeling is still used today, at least in part because of a sense that either high data quality, fine spatial sampling, or relatively simple geology is needed in order for inverse methods to work (e.g., Grad et al., 2006).

The advantages of inversion over forward modeling include the ability to (1) explore model space more thoroughly to better understand what structure is required by the data and what structure is consistent with the data, that is, model nonuniqueness; (2) quantify model errors and resolution; (3) handle larger data sets; and (4) fit the data appropriately given the data uncertainties. The Zelt and Smith (1992) algorithm allows for a compromise approach, best described as automated forward modeling, given the ability to focus on selected model parameters, as opposed to the entire model, as would be the case in trial-and-error forward modeling. The algorithm's inverse mode can be used to quickly determine the selected model parameter values so as to best satisfy the data from all

shots and receivers simultaneously, usually within a few iterations. Thus, this algorithm combines the parameter-selective aspect of forward modeling with the speed of inversion. In the remainder of this section, we briefly describe many of the algorithms available today, each with its own capabilities and limitations. There is likely a suitable traveltime inversion or tomography algorithm for just about every type of wide-angle data set.

Within the Eastern European community, methods for the analysis of wide-angle traveltime data have been developed that have not been adopted worldwide (e.g., Ilchenko, 1985; Pavlenkova, 1982). They share some characteristics with the algorithms used primarily in the engineering and petroleum industry for near-surface studies and refraction statics, for example, the generalized reciprocal method (Palmer, 1981), but they are rarely applied to crustal data and therefore will not be discussed here. Beginning in the 1980s, formal inverse theory was first applied to 2-D wide-angle traveltime inversion. About 10 years earlier, it had been applied to earthquake traveltime data to derive 3-D velocity models using only first arrivals (Aki and Lee, 1976; Crosson, 1976). Applying inversion to wide-angle data was delayed by the issues of data sparsity (e.g., typically only a few shots and/or receivers) and the desire to use both first and later arrivals (e.g., intracrustal and crust–mantle reflections and later refracted arrivals). Modeling later arrivals means having to include interfaces in the model parameterization and the resultant complexity of dealing with a mixed inverse problem. Some of the earliest published 2-D traveltime inversion algorithms were presented by Firbas (1981) and White (1989), which used a regular grid and only first arrivals, and Spence et al. (1985) and Huang et al. (1986), which allowed an irregular model grid and later arrivals.

In the 1990s, many 2-D and 3-D traveltime inversion and tomography algorithms were developed. We briefly describe the key features of the more widely used and innovative algorithms. Lutter and Nowack (1990) and Lutter et al. (1990) developed a 2-D inversion algorithm using a regular grid of nodes and numerical ray tracing that allows for the independent inversion of first arrivals and reflections for velocity and interface geometry, respectively. The Zelt and Smith (1992) 2-D algorithm is the exact opposite in many respects. An irregular grid of velocity and interface nodes can be used, and any type of refracted or reflected arrival can be inverted simultaneously for velocity and interface geometry (**Figure 8**). As mentioned earlier, the inversion can be applied to any subset of the total model parameters, facilitating an automated forward modeling approach and making it straightforward to incorporate prior information. Zelt (1994) and Clowes et al. (1995) used the Zelt and Smith (1992) 2-D algorithm to simultaneously invert refraction and reflection times from a network of 2-D profiles such that the model parameters at the intersection points were linked to ensure consistency. This approach can be used to infer 3-D structure from 2-D data and develop a starting model for the 3-D inversion of in-line and offline data (e.g., Zelt et al., 1999).

Hole (1992) developed a widely used 3-D first-arrival tomography algorithm using the Vidale (1990) forward modeling scheme and backprojection to solve for a smooth velocity field. Hammer et al. (1994) developed a 3-D first-arrival tomography algorithm specially suited to sparse data using a spectral, continuous function model parameterization. Toomey et al. (1994) developed a 3-D first-arrival tomography algorithm to obtain a smooth velocity field in which the velocity grid is 'draped' from an irregular bathymetric surface by vertically shearing the columns of nodes to accurately model the seafloor relief. Vertically sheared grids are particularly important for marine data, especially at mid-ocean ridges, where a large velocity discontinuity may exist. Forward modeling through this type of parameterization is straightforward using the shortest-path method (Toomey et al., 1994). Similar algorithms with sheared grids have been developed by Van Avendonk et al. (1998) and Korenaga et al. (2000), although they are limited to 2-D models, but include reflections and use the hybrid shortest-path/bending scheme described earlier. The main difference between the Van Avendonk et al. (1998) and Korenaga et al. (2000) algorithms is the former uses first arrivals that can turn above or below a reflecting interface at which there is no velocity discontinuity, whereas the latter only uses first arrivals that turn above the reflecting interface.

Lailly and Sinoquet (1996) developed a 2-D algorithm for inverting reflection times for a smooth velocity and interface model using the wavefront-tracking method of Podvin and Lecomte (1991). Zelt and Barton (1998) developed a 3-D first-arrival tomography algorithm using smoothing regularization and compared the results with those from the backprojection method of Hole (1992). The results showed that for the same level of fit to the data, regularized inversion can provide a smoother model. Zelt et al. (1999) developed a 3-D simultaneous refraction and reflection tomography algorithm solving for smooth velocities and multiple interfaces. McCaughey and Singh (1997) and Hobro et al. (2003) developed related 2-D and 3-D simultaneous refraction and reflection tomography algorithms that solve for smooth velocities and interfaces with the allowance for discontinuities across the layer boundaries.

Most of the algorithms described earlier are fairly general-purpose in nature and follow more or less from the objective function presented in the previous section. However, many more specialized algorithms have been developed. We describe a few of those here to give a sense of what is possible. Hole et al. (1992) developed an algorithm for determining a 3-D interface with known velocities above and below using first arrivals. Zhang et al. (1998) used the shortest-path method to develop a 2-D algorithm for refraction and reflection tomography in which only refracted arrivals originating above the reflecting interface are considered. A novel aspect of their approach is the inversion of traveltime curves instead of points, specifically average slowness and apparent slowness. They claim this balances the contribution from short and long ray paths and enhances resolution and convergence speed (Zhang and Toksöz, 1998). Rawlinson et al. (2001) and Rawlinson and Sambridge (2003b) developed an algorithm for the inversion of refraction and reflection times using a 3-D multilayered model parameterization. Interfaces are defined by a nonuniform node distribution, and velocities vary linearly with depth so ray paths are calculated analytically as piecewise circular arcs

using a shooting method. Trinks et al. (2005) presented a method for simultaneous refraction and reflection inversion using a 2-D layered model parameterization, which adapts to nonuniform ray coverage such that the cell size is inversely proportional to the local ray density.

1.15.15 Amplitude Modeling

The earliest analysis of crustal wide-angle data involved modeling the amplitudes, as well as the traveltimes, of the identifiable arrivals. In part this was because shots and receivers typically were so few that amplitudes were used to extract more information from the data than just using the traveltimes alone. Two of the most common methods used for amplitude modeling are the reflectivity method (Fuchs and Muller, 1971) and asymptotic ray theory (Cerveny et al., 1977). The former has the advantage of including the complete elastic wavefield for a 1-D model. The latter has the advantage of being applicable to laterally inhomogeneous (2-D) models. The drawbacks of ray methods are their infinite-frequency approximation and the need to specify the ray paths for each arrival type being modeled. These disadvantages are typically not a serious problem with crustal data, since it is usually only the large-scale amplitude trends of a few arrival types, such as the primary refractions and reflections, which are modeled.

To overcome some of the limitations of asymptotic ray theory, ray-based methods that incorporate finite-frequency effects were introduced, such as Gaussian beams (Cerveny et al., 1982; Weber, 1988) and Maslov theory (Chapman and Drummond, 1982). These methods can accurately predict the frequency-dependent amplitudes associated with triplications, diffractions, and geometric shadow zones. However, these methods have never experienced widespread use in crustal seismology because they lack the simplicity and predictability of asymptotic ray theory. Full-wavefield acoustic and elastic 2-D finite-difference algorithms (e.g., Levander, 1988; Robertsson et al., 1994) have been applied in a few crustal studies. Their heavy computational demand has meant that only a few simulations are typically run for the purpose of visual comparison with the observed seismograms (e.g., Gorman et al., 2006; Lendl et al., 1997; Parsons et al., 1996), although in the future, they will likely become more commonplace.

Although traveltime data are relatively insensitive to vertical velocity gradients and velocity discontinuities, such features may be well constrained by amplitude data (Braile and Smith, 1975). However, full-wavefield studies using models with fine-scale structure that is not resolved by traveltime data show that it can have a significant effect on wide-angle amplitudes (Lendl et al., 1997; Levander and Holliger, 1992) as will be discussed later. Thus, only the large-scale amplitude trends of primary arrivals should be modeled (e.g., Zelt and Forsyth, 1994). Velocity gradients and discontinuities derived through amplitude modeling may be used as constraints during traveltime inversion (e.g., Zelt et al., 1993). For amplitude modeling, it is common to plot synthetic seismograms, in which case the same trace spacing and amplitude scaling should be used for the synthetic and real data (e.g., Grad et al., 2006). A comparison of the observed and calculated amplitude–distance curves for individual phases allows a more quantitative comparison (e.g., Zelt and Forsyth, 1994; Zelt and White, 1995). As the number of shots and receivers used in typical wide-angle experiments has increased dramatically over the past 20 years, the resolution from traveltime data alone has also greatly improved. For this reason, and given the appreciation of the effects of fine-scale structure (Section 1.15.17), amplitude modeling is often ignored today.

1.15.16 S-Waves, Density, Attenuation, and Anisotropy

The majority of crustal wide-angle seismic studies today use only P-wave arrival times to constrain P-wave velocity structure. This is because P-wave arrival times are almost always the most reliable feature that can be extracted from crustal wide-angle data and their constraint on P-wave velocity is probably the most robust data–model–parameter relationship. Second, there is a sense that P-wave velocity models are the most important in terms of addressing the key geologic and tectonic questions in most crustal studies, although this may be a perception driven by the first reason. Although rare today, studies that go beyond the determination of 2-D and 3-D P-wave velocity models will likely become more common in the future given the need to justify new data acquisition and analysis when so much good data already exist from many sites around the world.

S-waves and converted phases are sometimes recorded well in wide-angle experiments, even by vertical-component geophones. This allows S-wave velocity models to be developed, typically using the same traveltime modeling and inversion algorithms described earlier. When combined with P-wave models, Poisson's ratio can also be estimated. Using S-wave velocities or Poisson's ratio in addition to P-wave velocities narrows the range of possible rock types in an interpretation (Christensen, 1996). Examples of using S-waves from wide-angle surveys include Gohl and Pedersen (1995), Carbonell et al. (1996), Musacchio et al. (1997), Darbyshire et al. (1998), Stoerzel and Smithson (1998), and Fernandez-Viejo et al. (2005).

In theory, rock densities could be inferred from amplitude modeling, but for reasons already discussed, amplitude modeling of wide-angle data is no longer common. Full-waveform modeling or inversion (discussed later) could be used to infer densities more reliably, but the typical procedure is to infer densities from P-wave velocities based on lab and field data compilations (Barton, 1986; Christensen and Mooney, 1995) in order to reduce the number of independent model parameters. It is fairly common to perform gravity modeling after obtaining a P-wave velocity model from wide-angle data, deriving the initial density model by converting the P-wave velocities to densities using an empirically derived velocity–density relationship (e.g., Christeson et al., 2001; Zelt and White, 1995). Brocher (2005) presented an empirical velocity–density relationship based on extensive compilations of velocity–density data.

The attenuation of seismic waves through anelasticity is a poorly understood phenomenon. The dimensionless quantity Q is a measure of the anelasticity experienced by seismic waves,

and as such, its value can be spatially mapped using seismic data. The two methods commonly used to estimate Q from seismic data involve modeling amplitudes directly or using spectral ratios. Amplitude methods should be viewed with caution for the reasons already stated regarding amplitude modeling. Estimates of Q from wide-angle data are rare but have been made by Braile (1977) and White and Clowes (1994) using amplitude methods, by Hashizume (1979), Zelt and Ellis (1990) and Wilcock et al. (1995) using spectral ratios, and by Li et al. (2006) using both methods on the same data.

Anisotropy estimates from wide-angle data are also rare but are most common in oceanic-crust and upper-mantle studies (e.g., Caress et al., 1992; Dunn and Toomey, 2001). One problem is that multicomponent crustal data are rarely recorded. Stoerzel and Smithson (1998) estimated crustal anisotropy from shear-wave splitting using three-component wide-angle data. The isotropic assumption made in the vast majority of wide-angle lithospheric studies has rarely been questioned or tested, but it may be an important effect, particularly in the sedimentary section and upper mantle. Its importance in 2-D and 3-D studies will depend on the type of anisotropy involved. For example, the effect of anisotropy due to subhorizontal fabric or layering could be significant when modeling coincident wide-angle and near-vertical data (Godfrey et al., 2002; Jones et al., 1999). From lab studies, Christensen and Mooney (1995) showed that anisotropy from preferred mineral orientation is likely to be most significant, as much as 10% or more, in upper and midcrustal metamorphic rocks. Sroda (2006) reported 8–10% azimuthal anisotropy for P-wave velocity in the upper crust using profiles of different orientation.

1.15.17 Fine-Scale Heterogeneities

Full-wavefield studies using models with wavelength- or subwavelength-scale heterogeneities have shown that the traveltimes, amplitudes, and wavefield can be significantly effected (e.g., Levander and Holliger, 1992; Muller et al., 1992), raising questions concerning the accuracy of results obtained using ray and wavefront-tracking methods. For traveltimes, there may be a structural form of anisotropy if there is a preferred orientation of the heterogeneities. Even without a preferred orientation, the traveltimes will likely not correspond to the bulk velocity, but will be biased toward a higher velocity when using first-arrival times. Either way, traveltime methods will still constrain large-scale heterogeneities, at least in a relative sense, but the absolute velocities may be biased with respect to the bulk velocities depending on the nature of the fine-scale structure and the seismic wavelengths.

Even more so than the traveltimes, the amplitudes and wavefield can be significantly altered depending on the nature of the fine-scale structure (Lendl et al., 1997; Levander and Holliger, 1992). For this reason, only the large-scale trend of amplitude-versus-offset variations or the overall relative amplitudes of different arrival types should be modeled when using velocity models derived from infinite-frequency methods (e.g., Zelt and Forsyth, 1994; Zelt and White, 1995). Methods for estimating stochastic parameters that describe the fine-scale structure have been developed (Poppeliers and Levander, 2004). This information can be used to add a stochastic fine-scale structure to a long-wavelength model derived from traveltimes and thereby allow a comparison between the observed and predicted seismograms using full-wavefield methods. Although usually limited by the computational requirements of full-wavefield methods, some trial-and-error forward modeling may be applied to refine the short- or long-wavelength model parameters (e.g., Gorman et al., 2006; Lendl et al., 1997). Alternatively, it may be possible to estimate the fine-scale structure deterministically given sufficiently high-quality data using full-wavefield inversion techniques (**Section 1.15.21**).

1.15.18 Joint Inversion

Wide-angle data can be jointly inverted with other data that depend on P-wave velocity. Coincident near-vertical reflection data can be used in several ways (Zelt, 1999). From stacked data, the reflector geometries and interval velocities can be used as prior information in the regularization to constrain a layered velocity model (e.g., Bosch et al., 2005). Alternatively, arrivals in prestack reflection data can be picked and inverted jointly with the wide-angle data. This approach will provide the most thorough use of the reflection data in terms of additional model constraint, but it is often difficult to pick weak events in prestack data. The most common approach is to pick reflections from a stacked reflection section and invert these data simultaneously with the wide-angle data by modeling zero-offset reflections (e.g., McCaughey and Singh, 1997; Zelt et al., 2003). There are potential pitfalls when using coincident reflection data: First, the near-vertical reflection event may be incorrectly correlated with the corresponding wide-angle event or layer boundary; Jaiswal et al. (2006) presented a way to avoid this problem. Second, as previously mentioned, errors and model distortion will occur if there is transverse isotropy, since wide-angle data are primarily sensitive to horizontal velocities and near-vertical reflection data are primarily sensitive to vertical velocities (Godfrey et al., 2002; Jones et al., 1999).

The second type of data that can be jointly inverted with wide-angle data in a straightforward manner is local and regional earthquake body-wave arrival times. An algorithm to jointly invert active and passive data needs to be 3-D and needs to be able to determine earthquake hypocenters in addition to velocities, either simultaneously or by iterating back and forth between locations and velocities. Benz et al. (1996), Symons and Crosson (1997), and Ramachandran et al. (2005) each developed similar algorithms to simultaneously invert active and passive data; the former used the forward calculation method of Podvin and Lecomte (1991), while the latter two used the Vidale (1990) scheme. Hole et al. (2000b) advocated a nonsimultaneous approach in their determination of 3-D velocity and hypocenters using active and passive data.

The close relationship between seismic velocity and density (Barton, 1986; Brocher, 2005) lends gravity data to a joint inversion with wide-angle data. Nielsen and Jacobsen (2000)

used the Zelt and Smith (1992) algorithm as the basis for a simultaneous inversion of refraction and reflection times with gravity data to derive a layered 2-D crustal model. Korenaga et al. (2001) carried out a joint inversion of traveltime and gravity data in which error propagation from the velocity model to the predicted gravity anomalies was taken into account. Roy et al. (2005) jointly inverted first arrivals and gravity data using a global optimization scheme to derive a smooth 2-D layered model. 3-D velocity and density are jointly inverted by Parsons et al. (2001). One important issue in joint seismic-gravity inversion is whether the coefficients of the velocity–density relationship are fixed or determined as part of the inversion.

1.15.19 Model Assessment

Model assessment is used to explore nonuniqueness, resolution, and model errors. Different assessment techniques will be appropriate depending on the type of data and model parameterization. Linear methods assume it is valid to consider only a local neighborhood of the final model within which the model–data relationship is linear. Nonlinear methods involve additional nonlinear inversions of the real data and synthetic data using the true source–receiver geometry of the experiment. The former methods tend to be quick and easy to apply, although potentially less reliable depending on the nonlinearity of the problem. The latter methods tend to be computationally intensive. Zelt (1999) and Rawlinson and Sambridge (2003a) described many of the techniques in use today; we will highlight only the most popular. Zelt et al. (2006a) applied several different techniques to the same 3-D data set.

The simplest form of model assessment is to examine the ray-path coverage, through either plots of ray paths or 'hit counts' (the number of rays sampling each model cell or node). These can be misleading since a nonuniform distribution of ray angles may provide less independent model constraint than expected from the number of rays alone. Toomey et al. (1994) used a measure called derivative weight sum (DWS) equal to the sum of the partial derivatives for each model parameter. This is more meaningful than hit count since it weights the contribution from each ray according to the parameter's sensitivity to that ray. However, it also fails to account for the degree of independence within the ray-path set. Other common linear assessment measures include the diagonals of the posterior resolution and covariance matrices (e.g., Zelt and Smith, 1992). These are more precise measures since they account for the independence of the ray-path set, but they are best used in a relative sense as opposed to absolute sense, since they do not account for the nonlinearity of the problem. Rows of the resolution matrix, known as resolution kernels, provide a spatial sense of the averaging or smearing of the true structure by the model (e.g., White, 1989; Zelt, 1999). Probably the most precise linear assessment method uses singular-value decomposition (SVD) since it is able to quantify the nature and degree of model constraint through construction of an orthogonal set of basis vectors that span model space, each with a specified weight in the model reconstruction (e.g., White, 1989). However, SVD is generally limited to relatively small problems, although approximate methods for large problems have been developed (e.g., Scales, 1989).

A parameter-selective algorithm such as the Zelt and Smith (1992) approach allows for a nonlinear assessment of the error bounds and spatial resolution for a single model parameter, or set of parameters (Zelt, 1999). In these tests, the real data and synthetic data are inverted in the same way that the final model was derived, allowing the full nonlinearity of the problem to be accounted for, including trade-offs between model parameters (e.g., Christeson et al., 1999; Holbrook et al., 1994; Zelt and White, 1995). These tests are time-consuming and only representative parameters can be tested in this way. A fine-grid tomographic approach can facilitate a similar type of test. For example, Zelt and Barton (1998) examined one region of a model where there was significant lateral structure even though the ray coverage was low in this area. They added regularization to the inversion to force that region to remain laterally homogeneous and thereby establish the required trade-offs elsewhere in the model.

Other nonlinear assessment techniques include trying different starting models, different values of the free parameters in the objective function, and exclusion of subsets of the data considered less reliable (e.g., Zelt et al., 2006a). Using different model parameterizations and different inversion algorithms can be particularly illuminating, especially when one algorithm seeks a model that satisfies all prior information and preconceived notions of what is geologically reasonable and one algorithm seeks the minimum-structure model (Zelt et al., 2003; **Figure 8**). In this way, it is possible to determine what model structure is consistent with the data to facilitate hypothesis testing while at the same time establishing what model structure is required by the data. White and Boland (1992), Korenaga et al. (2000), Holbrook et al. (2001), Zelt et al. (2003), Levander et al. (2005), and Grad et al. (2006) (**Figure 9**) applied different forward and inversion algorithms to the same wide-angle data.

One of the most common forms of nonlinear model assessment for wide-angle data is the checkerboard test for estimating model resolution (e.g., Day et al., 2001; Evangelidis et al., 2004; Morgan et al., 2002; Schlindwein et al., 2003). In these tests, an alternating pattern of high and low anomalies is superimposed on a reference model, and synthetic data are calculated for the 'checkerboard' model. These data are inverted using the same starting model and source–receiver geometry as real the data inversions and the recovered model will closely resemble the checkerboard pattern in regions of good constraint. Results from anomaly patterns with different polarity, registration, and orientation should be averaged to reduce the effects of changing ray coverage due to the nonlinearity of the problem (Zelt, 1998). Anomaly patterns for velocity and depth nodes can be treated separately or simultaneously for mixed problems (e.g., Zelt et al., 1999).

The most computationally intensive form of model assessment involves a Monte Carlo procedure. Many realizations are performed in which randomized data are inverted using randomized starting models. The resulting models are used to compute posterior model covariance and resolution estimates (Korenaga et al., 2000; Zhang and Toksöz, 1998; Zhang et al., 1998; **Figure 10**). This approach may not be feasible computationally for large problems.

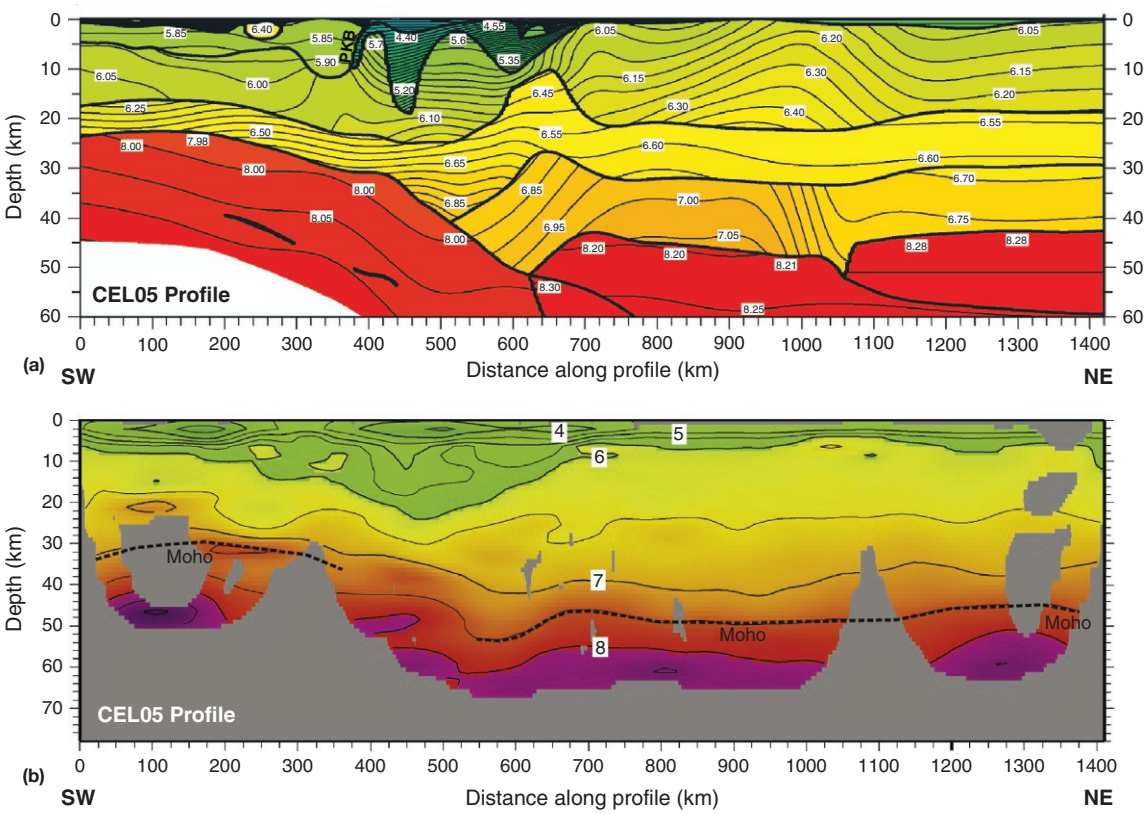

Figure 9 Example from the CELEBRATION 2000 experiment extending from Hungary to Russia in which two very different modeling approaches were applied to the same wide-angle data (Grad et al., 2006). Data from 26 explosions were collected by 360 portable recorders along the profile. (a) P-wave model obtained by forward modeling of refraction and reflection traveltimes and amplitudes using a layered parameterization with a smooth velocity field between discontinuities using the method of Cerveny et al. (1977). (b) Model obtained by traveltime inversion using only first arrivals in which a smooth, minimum structure was sought using the method of Zelt and Barton (1998). Velocity contours are labeled in km s^{-1}. The 7.5 km s^{-1} contour was used as a guide to interpret the Moho in (b).

1.15.20 Wide-Angle Migration

Conventional narrow-angle reflection and wide-angle seismology methods are beginning to merge in the academic community, as the number of shots and the station density in an average wide-angle survey has increased. Frequently, intracrustal, Moho, and sub-Moho reflections can be imaged using migration techniques applied to wide-angle data (Henstock and Levander, 2000; Henstock et al., 1997; Holbrook et al., 1992; Lafond and Levander, 1995; McMechan and Fuis, 1987; Milkereit et al., 1990; Morozov and Levander, 2002; Van Avendonk, 2004). However, the velocity model for wide-angle migration needs to be more accurate than for conventional migration, as minor lateral velocity errors are compounded for travel paths with large horizontal components. Typically, traveltime inversion and tomography provide velocity models suitable for wide-angle migrations (Zelt et al., 1998). The greatest benefit from wide-angle migration, as with conventional reflection processing, is the ability to use the seismic wavefield to image wavelength-scale structure without having to explicitly identify, pick, and model individual arrivals within the wavefield, other than the primary phases already used in the traveltime modeling. Resolution reduces to about half of the vertical wavelength, which for waves traveling as far horizontally as vertically is significantly larger than for vertically incident waves only.

A kinematic form of wide-angle migration can be carried out using a ray-tracing algorithm in which wide-angle reflection picks are modeled using floating reflecting surfaces (e.g., Holbrook et al., 1994; Stoerzel and Smithson, 1998; Wissinger et al., 1997; Zelt and White, 1995). These reflectors are typically relatively short interfaces with no associated velocity structure so that they 'float' within the velocity field of the model as defined by previous traveltime modeling of other phases. When a number of floating reflectors from different shots or receivers coalesce and align, then one can be confident that real structure is being imaged (e.g., Zelt and Forsyth, 1994).

1.15.21 Wavefield Inversion

Among others, Beylkin (1985), Beylkin and Burridge (1990), Tarantola (1984), Mora (1988), Pratt et al. (1996), and Pratt et al. (1998) approached the active seismic imaging problem as wavefield inversion, in which the image of the subsurface is defined as combinations of the perturbations of the material properties. For the constant density acoustic case, this image is

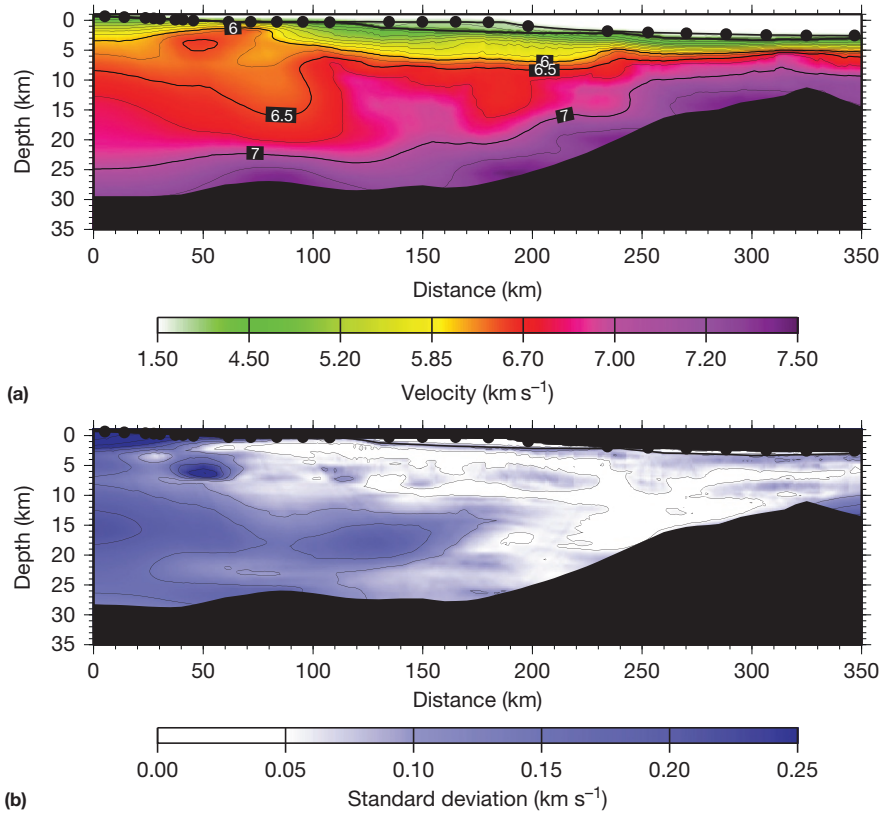

Figure 10 Example of model assessment using a nonlinear Monte Carlo procedure to estimate model variance (Korenaga et al., 2000). (a) P-wave velocity model for the southeast Greenland continental margin obtained by traveltime inversion of Pg and PmP arrivals recorded at 18 ocean-bottom instruments and eight land stations. This model was obtained by averaging 100 Monte Carlo ensembles. (b) Corresponding standard deviation for velocity and depth nodes; the standard deviation of the Moho is indicated by the width of the gray zone at the base of the crust.

the field $\delta c(x)/c_0(x)$. Wavefield inversion, despite its computational costs, has several advantages over migration for image formation: (1) Ideally, one is calculating the correct amplitudes of the material perturbations; (2) the source time function, $f(t)$, can be determined as part of the solution rather than being estimated independently; (3) at least theoretically, the development provides formal resolution estimates; and (4) perhaps most importantly, depending upon how one preconditions the data, both the background velocity field and the high-frequency fluctuation field can be estimated. The former is often referred to as waveform tomography and is applied to forward-scattered first arrivals with the backscattered field muted (e.g., Pratt et al., 1998); the latter is the reflection inversion and the data are preconditioned by removing the first arrivals. As in the previous section, Beylkin (1985) and Beylkin and Burridge (1990) cast the inverse problem in terms of high-frequency asymptotics and showed that the inversion integrals are generalized inverse Radon transforms. This formalism was developed by Bostock et al. (2001) for inversion of teleseismic data. Tarantola's (1984) development relies on inverse theory and, being the most general, is repeated here. Letting G again be Green's function and L the wave operator, we can write

$$\mathrm{p}(x_r, t, x_s) = \mathrm{G}(x_r, t, x_s, 0)^{*} f(t) \qquad [51]$$

and

$$\mathbf{p} = \mathbf{q}(\mathrm{c}, \mathrm{f}) \qquad [52]$$
$$\mathbf{p} = \mathbf{q}(\mathrm{m})$$

with $\mathrm{m} = (\mathrm{c}, \mathrm{f})^{\mathrm{T}}$ the vector of model parameters and $\mathbf{p}$ the vector of predicted observations. We can define the covariance matrix of the observations as

$$C_{\mathrm{P}}(x_r, t, x_s | x_r', t', x_s') = \sigma_{\mathrm{rs}}^2 \delta_{\mathrm{rr}'} \delta_{\mathrm{ss}'} \delta_{\mathrm{tt}'} \qquad [53]$$

Tarantola (1984) defined the covariance matrix of the model as the expected variances in the solution based on prior information and described them with a Gaussian error model:

$$C_{\mathrm{cc}}(x, x') = \sigma_{\mathrm{c}}^2 \exp\left(-\frac{1}{2}\left(\frac{(x-x_1')^2 + (x_2-x_2')^2}{a_{\mathrm{H}}^2} + \frac{(z-z')^2}{a_z^2}\right)\right)$$
$$C_{\mathrm{ff}}(t, t') = \sigma_{\mathrm{f}}^2 \exp\left(-\frac{1}{2}\left(\frac{(t-t')^2}{T_{\mathrm{f}}^2}\right)\right) \qquad [54]$$

with cross variances zero and a_{H}, a_z, and T_{f}, characteristic correlation lengths in the horizontal, vertical, and time coordinates. We note that many geologic structures have self-affine spatial covariance functions and take the form of the von Kármán function (e.g., Holliger and Levander, 1992). The a priori covariance matrix is then

$$C_{\mathrm{m}} = \begin{pmatrix} C_{\mathrm{cc}} & 0 \\ 0 & C_{\mathrm{ff}} \end{pmatrix} \quad [55]$$

Our initial guess of the model is

$$\mathbf{m}_0 = \begin{pmatrix} \mathbf{c}_0 \\ \mathbf{f}_0 \end{pmatrix} \quad [56]$$

and note that the observations do not fit the initial model

$$\mathbf{p}_0 \neq \mathbf{q}(\mathrm{m}_0) \quad [57]$$

We can define the data residual as the difference between the observations and the predictions:

$$\delta\mathbf{d}(\mathbf{m}) = \mathbf{p}_0 - \mathbf{q}(\mathbf{m}) \quad [58]$$

We wish to minimize

$$\begin{aligned} 2S(\mathbf{m}) &= ||((\mathbf{p}_0 - \mathbf{p}), (\mathbf{m}_0 - \mathbf{m}))||^2 \\ &= (\mathbf{p}_0 - \mathbf{p})^* \mathrm{C_p} (\mathbf{p}_0 - \mathbf{p}) + (\mathbf{m}_0 - \mathbf{m})^* C_{\mathrm{m}} (\mathbf{m}_0 - \mathbf{m}) \\ 2S(\mathbf{m}) &= \delta\mathbf{d}\left(\vec{\mathbf{m}}\right)^* \mathrm{C_p} \delta\mathbf{d}\left(\vec{\mathbf{m}}\right) + (\mathbf{m}_0 - \mathbf{m})^* C_{\mathrm{m}} (\mathbf{m}_0 - \mathbf{m}) \end{aligned} \quad [59]$$

where asterisk denotes complex conjugate. The minimum solution occurs where the gradient of S with respect to the model coordinates vanishes, giving

$$(\mathbf{m}_0 - \mathbf{m}) = C_{\mathrm{m}} \nabla_{\mathrm{m}} \delta\mathrm{d}(\mathbf{m})^* C_{\mathrm{p}}^{-1} \delta\mathbf{d}(\mathbf{m}) \quad [60]$$

Tarantola (1984) generalized this expression by adding $C_{\mathrm{m}} \nabla_{\mathrm{m}} \delta\mathbf{d}(\mathbf{m})^* C_{\mathrm{p}}^{-1} \nabla_{\mathrm{m}} (\delta\mathbf{d}(\mathbf{m})(\mathbf{m}_0 - \mathbf{m}))$ to both sides, giving

$$\begin{aligned} (\mathbf{m}_0 - \mathbf{m}) &= \left(I + C_{\mathrm{m}} \nabla_{\mathrm{m}} \delta\mathbf{d}(\mathbf{m})^* C_{\mathrm{p}}^{-1} \nabla_{\mathrm{m}} \delta\mathrm{d}(\mathbf{m})\right)^{-1} \\ &\quad \times C_{\mathrm{m}} \nabla_{\mathrm{m}} \delta\mathbf{d}(\mathbf{m})^* C_{\mathrm{p}}^{-1} (\delta\mathbf{d}(\mathbf{m}) + \nabla_{\mathrm{m}} \delta\mathbf{d}(\mathbf{m})(\mathbf{m}_0 - \mathbf{m})) \\ (\mathbf{m}_0 - \mathbf{m}) &= W\Big(C_{\mathrm{m}} \nabla_{\mathrm{m}} \delta\mathbf{d}(\mathbf{m})^* C_{\mathrm{p}}^{-1} (\delta\mathbf{d}(\mathbf{m}) \\ &\quad + \nabla_{\mathrm{m}} \delta\mathbf{d}(\mathbf{m})(\mathbf{m}_0 - \mathbf{m}))\Big) \end{aligned} \quad [61]$$

which he described as a 'beautiful' but 'useless' equation, as W is too large to compute for realistic problems. Of the various approximations to W, the simplest of these is a gradient algorithm for an iterative solution to the nonlinear seismic problem:

$$\begin{aligned} W_{\mathrm{app}} &\approx \alpha I \\ \mathbf{m}_{k+1} &= m_k + \alpha\Big(C_{\mathrm{m}} \nabla_{\mathrm{m}} \delta\mathbf{d}(\mathbf{m}_k)^* C_{\mathrm{p}}^{-1} \delta\mathbf{d}(\mathbf{m}_k) - (\mathbf{m}_k - \mathbf{m}_0)\Big) \end{aligned} \quad [62]$$

Other approximate iterative solutions include using the diagonal or banded diagonal forms of W. In these equations, the forward model can be solved by any scheme capable of producing the field at any point, for instance, time- or frequency-domain finite-difference or finite-element methods.

In a series of papers, Pratt and his colleagues developed a practical inversion scheme along similar lines based on 2-D frequency-domain finite-difference forward modeling. They assume that the a priori covariance is infinite. The frequency-domain wave equation can be written as an operator:

$$\begin{aligned} \left[\nabla^2 + \frac{\omega^2}{c^2(x)}\right] p(x, x_s, \omega) &= f(x, x_s, \omega) \\ LP(x, x_s, \omega) &= f(x, x_s, \omega) \\ \mathrm{P}(x, x_s, \omega) &= L^{-1}\mathrm{f}(x, x_s, \omega) \end{aligned} \quad [63]$$

where L is the discrete frequency-domain operator dependent upon the model parameters and p is a function of the model parameters. Since L^{-1} generates p for a given source or collection of discrete sources f, the columns of L^{-1} are Green's functions for the model. Restricting the model vector to material perturbations, we can write eqn [59] in the more familiar form:

$$2S(\mathbf{m}) = \delta\mathbf{d}(\mathbf{m})^T \delta\mathbf{d}(\mathbf{m})^* \quad [64]$$

Minimizing this with respect to m using a gradient method gives

$$\begin{aligned} m^{(k+1)} - \mathrm{m}^{(k)} &- \alpha \nabla_m S\left(m^{(k)}\right) \\ m^{(k+1)} - \mathrm{m}^{(k)} &\Big| \alpha \mathrm{Re}\left\{ \left[\frac{\partial P}{\partial m^{(k)}}\right]^{\mathrm{T}} \delta\mathrm{d}\left(\mathrm{m}^{(k)}\right)^* \right\} \\ m^{(k+1)} - \mathrm{m}^{(k)} &\Big| \alpha \mathrm{Re}\left\{ \left[J^{(k)}\right]^{\mathrm{T}} \delta\mathrm{d}\left(\mathrm{m}^{(k)}\right)^* \right\} \end{aligned} \quad [65]$$

where J is the Jacobian matrix of Fréchet derivatives of the calculated field, p_i, with respect to the model parameters at the kth iteration, $m_j^{(k)}$. The last equation demonstrates several principles of imaging: the product of the frequency-domain data residuals with the derivatives of the estimated field constitutes a cross correlation. The conjugate of the data residuals implies that the residuals are propagated in a time-reversed sense. The cross correlation finds parts of the observed field that are missing from the predicted field. In particular, Pratt et al. (1998) showed that the Jacobian finds those parts of the first-order scattered field that are present in the data but not in the model. Moreover, noting that

$$\begin{aligned} &\frac{\partial L}{\partial m_i}\mathrm{p} + \frac{\partial \mathrm{P}}{\partial m_i} = 0 \\ &\frac{\partial \mathrm{P}}{\partial m_i} = L^{-1}\left[\frac{\partial L}{\partial m_i}\mathrm{p}\right] = L^{-1}\mathrm{f}^{(i)} \\ &\mathcal{F} = L^{-1}\left[f^{(1)} \cdots f^{(n)}\right] \\ &\mathcal{F} = L^{-1}F \end{aligned} \quad [66]$$

and comparing to eqn [65], we see that the Jacobian can be interpreted as a series of virtual sources applied at the n parameter locations. The derivative of L with respect to the parameters turns eqn [65] to

$$\begin{aligned} m^{(k+1)} &= \mathrm{m}^{(k)} + \alpha \mathrm{Re}\left\{ \left[L^{-1}F\right]^{\mathrm{T}} \delta\mathrm{d}\left(\mathrm{m}^{(k)}\right)^* \right\} \\ m^{(k+1)} &= \mathrm{m}^{(k)} + \alpha \mathrm{Re}\Big\{ \left[F^{(k)}\right]^{\mathrm{T}} \left[L^{-1}\right]^{\mathrm{T}} \delta\mathrm{d}\left(\mathrm{m}^{(k)}\right)^* \Big\} \end{aligned} \quad [67]$$

A number of authors have noted that the first iterate of [67] is equivalent to prestack migration: The data residual is calculated as the predictions between the smooth velocity and impedance field (i.e., there are no backscattered waves predicted), so the residual is just the backprojected set of observations:

$$\begin{aligned} \delta\mathrm{m}^{(1)} &= \alpha \mathrm{Re}\left\{ \left[F^{(0)}\right]^{\mathrm{T}} \delta\mathrm{d}\left(\mathrm{m}^{(0)}\right)^* \right\} \\ \delta\mathrm{m}^{(1)} &= \alpha \mathrm{Re}\left\{ \left[F^{(0)}\right]^{\mathrm{T}} \left[L^{-1}\right]^{\mathrm{T}} \delta\mathrm{d}\left(\mathrm{m}^{(k)}\right)^* \right\} \end{aligned} \quad [68]$$

1.15.22 Wavefield Inversion Examples

We show three examples of wavefield inversion, one synthetic and two from field experiments. Figure 11 shows an example

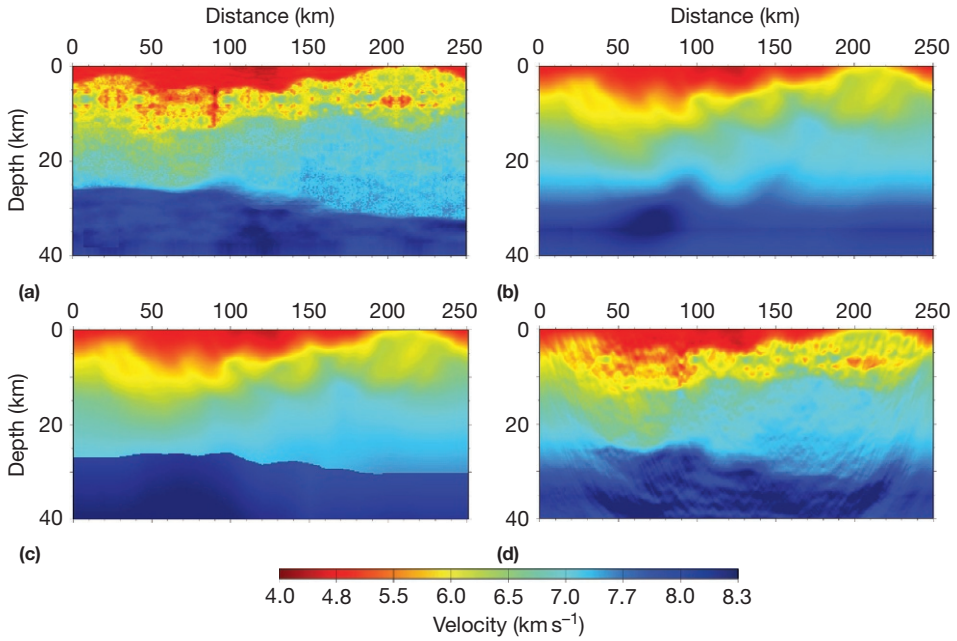

Figure 11 Blind test of traveltime and waveform inversion (Hole et al., 2005). (a) True model used to compute 2-D viscoelastic full-wavefield data for a refraction/wide-angle reflection survey. (b) Model derived from traveltime tomography using only first arrivals. (c) Model derived from traveltime inversion using first arrivals and wide-angle reflections from the Moho. The traveltime models are smooth but robust versions of the true model. (d) Model derived from waveform tomography using (b) as the starting model (Brenders and Pratt, 2007). The waveform model significantly improves the spatial resolution over the traveltime result and matches many details of the true model in (a).

of waveform tomography applied to a synthetic crustal data set using Pratt's method (Brenders and Pratt, 2007). The synthetic data set was developed using a viscoelastic finite-difference method for a blind test of traveltime and waveform tomography models for a Commission on Controlled Source Seismology workshop (Hole et al., 2005). Long and short spatial wavelength structures were included using a variety of statistical descriptions of crustal rocks to make the model and data set as realistic as possible in terms of acquisition geometry, velocity heterogeneity, and wave propagation. Traveltime tomography recovers the large-scale structure quite well, and waveform tomography does a surprisingly good job of recovering the finer-scale structure.

Figure 12 shows an example of waveform tomography applied to dense ocean-bottom seismometer data from the Nankai Trough (Operto et al., 2006). Again, traveltime tomography defines the long-wavelength structure, and waveform tomography resolves the fine-scale structure by inverting frequencies up to 15 Hz.

Environmental geophysics is used to characterize the shallow subsurface to locate and map the underground flow of pollutants or to estimate groundwater reserves. Figure 13 is an example of traveltime and waveform tomography results using high-resolution seismic data acquired at a groundwater contamination site in Ogden, Utah. The seismic target is a paleochannel incised in a clay layer at a depth of a few to 15 m below the surface and filled with low-velocity alluvium. The clay layer acts as an aquitard stopping descent of dense nonaqueous phase liquid (DNAPL) pollutants with the channel acting as a collection point for the pollutants. The geophysical problem was to identify the top of the clay layer and characterize the channel. Separate 3-D seismic reflection and refraction surveys as well as vertical seismic profiles were performed at the site. A 0.223 caliber rifle was used as the seismic source, and geophones were spaced 30 cm apart. Figure 13(b) shows the image of the subsurface made using Pratt's method applied to surface and borehole seismic data collected along the axis of the channel (Gao et al., 2006). The degree of lateral and vertical heterogeneity observed is surprising; velocities vary by a factor of 2–3 laterally and by an order of magnitude vertically. This poses a serious problem for conventional poststack seismic imaging methods.

1.15.23 Future Directions

The trends in data acquisition in both the industrial and academic communities are toward higher spatial density recording using an ever-increasing number of instruments. Industrial acquisition now largely consists of 3-D surveys, whereas equipment and acquisition budgets restrict academia to 2-D and a small number of 3-D surveys. The US academic community now has ~3000 matched channel available for land controlled-source work (including three-component instruments) through the IRIS PASSCAL facility. This is a factor of 5 greater than the total number of (unmatched) channels available from all North American academic sources in the early 1990s. The US marine community now has more than a hundred ocean-bottom seismographs for active-source work available from the national OBS Instrument Pool. The US academic fleet has just acquired its first seismic vessel designed for 3-D surveying. Similar instrument pools, of comparable size, exist or are in development in Europe and Asia. Data volumes are increasing rapidly in size, requiring more and more automation for preprocessing and image formation and analysis. Combined with Moore's law increase in computer speed, memory, and storage, the automatic

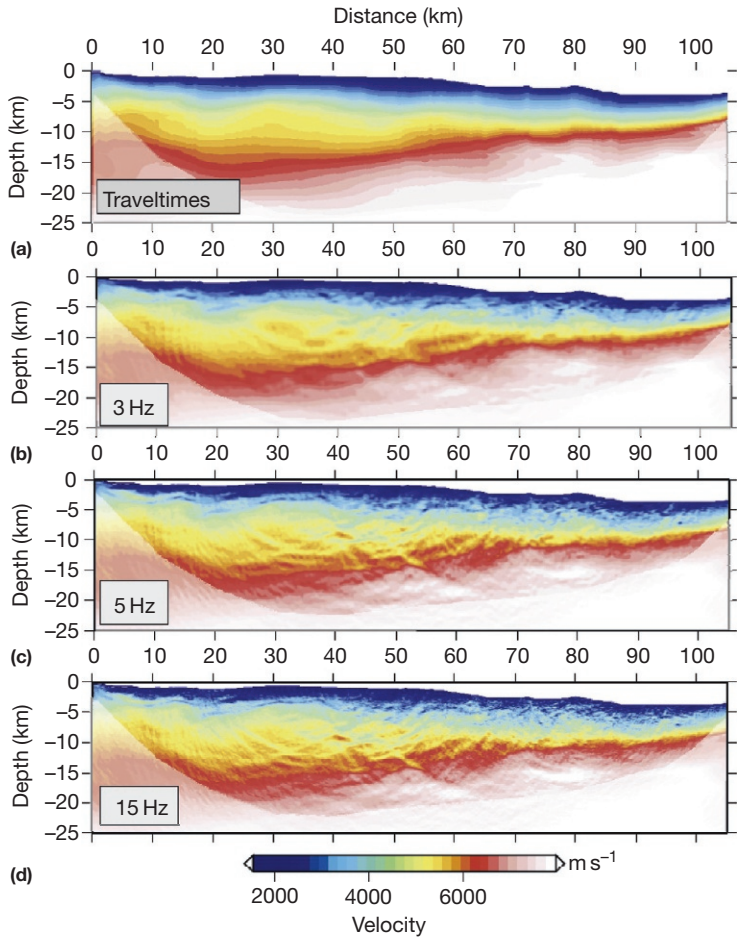

Figure 12 Example of waveform tomography applied to dense ocean-bottom seismometer data from the Nankai Trough (Operto et al., 2006). The vertical-component seismograms of 93 instruments were used in the inversions, windowed to 1–3 s starting at the first-arrival time, depending on the water depth. (a) P-wave model derived from traveltime tomography used as the starting model for waveform tomography. (b)–(d) Models derived from waveform tomography at 3, 5, and 15 Hz, as labeled.

inversion routines described in **Section 1.15.21** are likely the path to the future.

Full-waveform inversion for 1-D models has been applied for many years to both reflection and wide-angle data, the latter particularly in oceanic and gas hydrate studies (Minshull et al., 1994; Shaw and Orcutt, 1985). Sun and McMechan (1992) and Pratt et al. (1996) applied 2-D elastic and acoustic full-waveform inversion to synthetic wide-angle data. Full-waveform inversion of real wide-angle data for 2-D models is just beginning to be applied (e.g., Chironi et al., 2006; Operto et al., 2006; Ravaut et al., 2004; Shipp and Singh, 2002). These techniques are currently limited to 2-D acoustic models, primarily for computational reasons. They are nonlinear gradient methods that require a good starting model usually obtained through traveltime methods. Broadband, low-frequency data, like that collected by Spitzer and White (2005) for subbasalt imaging, are ideal for waveform inversion. Brenders and Pratt (2007) presented a comparison of velocity models derived from first-arrival traveltime tomography and waveform tomography for a realistic set of synthetic wide-angle data in a blind test; Hole et al. (2005) presented a comparison of the same waveform-derived model with a velocity model derived from combined first-arrival and Moho-reflection traveltime inversion. These comparisons suggest that waveform methods have the potential to provide roughly an order-of-magnitude increase in spatial resolution over traveltime methods (**Figure 11**). Extending these methods to elastic models and 3-D, although not a major theoretical leap, will be a numerical analysis and computational challenge.

For lithospheric studies, the need for flexible, general-purpose traveltime inversion and tomography algorithms will remain, both as primary modeling tools and to provide long-wavelength starting models for higher-resolution wavefield techniques. We have already discussed the likelihood that S-wave, attenuation, and anisotropy studies will become more commonplace in the future, although they have yet to be employed commonly in academic investigations.

For traveltime methods, formal treatment of Fresnel zones (Watanabe et al., 1999), adaptation of frequency-dependent sensitivity kernels from global seismology (Dahlen et al., 2000), and wave equation-based modeling (Pyun et al., 2005) will reduce the need for regularization and improve the stability of gradient methods. The derived models will contain more structure and increased resolution as a result of more accurately honoring the physics of wave propagation.

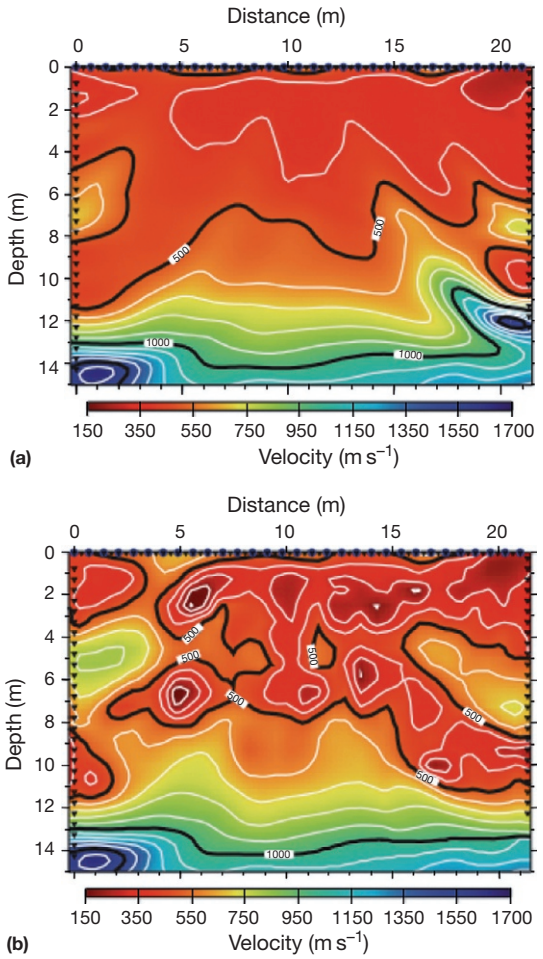

Figure 13 (a) Characterization of the shallow subsurface at a groundwater contamination site. Velocity model derived from first-arrival traveltime tomography from a VSP/surface seismic experiment along the axis of a buried paleochannel that acts as a trap for groundwater contaminants. A smoothed version of the model was used as the starting model for the waveform inversion. (b) Final velocity model derived from waveform tomography using the method of Pratt (1999) and Pratt and Shipp (1999). The velocity varies laterally by a factor of 2–3 and changes vertically by an order of magnitude over 15 m. The smallest features laterally are ~2–3 m, roughly the theoretical resolution obtainable. The sediments along the axis of the channel, above ~14 m depth, show a surprising degree of heterogeneity. Reproduced from Gao F, Levander A, Pratt RG, Zelt CA, and Fradelizio G-L (2006) Waveform tomography at a ground water contamination site: VSP-surface dataset. *Geophysics* 71: H1–H11, with permission from Society of Exploration Geophysics.

This will be particularly true for near-surface studies in which the length scales of heterogeneities are comparable with or smaller than the seismic wavelengths (e.g., Zelt et al., 2006a).

Very efficient simulations of 2-D and 3-D viscoelastic wave propagation at realistic frequencies are needed for the forward modeling component of wavefield inversion schemes. The global seismology community also shares these needs. Advances have been made toward computing realistic global seismograms in laterally variable viscoelastic media (e.g., Komatitsch and Tromp, 1999, 2005). Simulating wave propagation using model parameterizations that incorporate mathematical descriptions of rock properties such as fractures, porosity, saturation, gas concentration, and partial melt (e.g., Aldridge et al., 2004) will help ensure that seismic methods will continue to play a role in addressing the most relevant Earth science problems.

Many problems of interest to academic Earth scientists require relatively high-resolution imaging across a broad range of scales, from the surface geology through the crust and into the upper mantle. Highly detailed images of the crust and the top of the mantle are only available from controlled-source imaging, whereas much of the lithospheric mantle and deeper can only be imaged practically with earthquake sources. Perhaps one of the most interesting future research directions facing the academic community is the combined inversion of controlled-source data with teleseismic body-wave data. This poses a number of challenges, as the bandwidths recorded, the scales of spatial sampling and resolution, and the source and receiver configurations used in the various experiments are very different.

Acknowledgments

The author thanks Gian L. Fradelizio and Stephen Clark for assistance in making figures.

1.16.1 Introduction

The discovery of plate tectonics fundamentally changed scientists' view of the Earth, generating an entirely new set of precepts for how continents form and evolve over time. Plate tectonics elevated the central role of the continental 'lithosphere' as opposed to the 'crust,' and it established a direct relationship between dynamic processes deep in the mantle and shaping of continents. The continental lithosphere is now recognized to be a complex agglomeration of accreted and tectonically modified lithospheric blocks that are the repository of most of the Earth's history. Ironically, the seafloor that provided us with much of the

 http://dx.doi.org/10.1016/B978-0-444-53802-4.00014-2

proof of plate tectonics is nowhere older than about 200 Ma and thus contains no information on the earlier geologic history of the Earth. As the theory of plate tectonics was refined and its implications for continental dynamics and evolution better understood, it became increasingly evident that an essential key to understanding the continents lay in our ability to image in detail the 3-D structures of the lithospheric and sublithospheric mantle.

Passive array seismology, notably portable broadband seismology, emerged over the past 25 years to fill the void between detailed active source crustal seismology and low-resolution seismology based on widely dispersed stations of the global seismic network (GSN), neither of which was properly suited to the study of continental lithospheric mantle. Despite the demand for new seismic tools to study lithosphere-scale structure of continents, however, passive array seismology would not exist today without key technical breakthroughs. Lithosphere-scale imaging has been revolutionized in the past 25 years by the advent of portable high-fidelity low-power 24-bit digital seismic systems, including portable broadband sensors with wide frequency bandwidth and high dynamic range. This new instrumentation provides the tools for seismic studies broadly termed 'passive array experiments.' Passive array experiments involve the deployment of tens or even hundreds of instruments, broadband and short-period, each of which is capable of operating unattended for months to years at a time in the most remote regions of the Earth. The term 'passive' derives from the fact that these stand-alone arrays of self-sufficient stations record seismic data from earthquakes around the world continuously over periods of months and even years at a time. These passive array earthquake recordings comprise the essential data for analyzing lithospheric structure.

While fixed array seismology emerged in the 1960s with the construction of the US Department of Defense facilities such as Large Aperture Seismic Array (LASA) in Montana (e.g., Aki et al., 1976) and NORSAR in Norway to monitor nuclear explosions, portable array seismology based on earthquake observations (as opposed to timed explosions) is a recent phenomenon. Prior to the development of low-power portable array instrumentation, lithospheric studies were confined largely to the crust: with very few exceptions (long profiles from US and Soviet nuclear blasts), high-resolution imaging of deeper structures in the continental lithosphere and in the mantle beneath the lithosphere was largely beyond the means of existing instrumentation and methods. The precursors to modern passive array seismology were found at a handful of institutions that engaged in portable seismic experiments with in-house instrumentation of limited functionality. For most groups, severe constraints were imposed by aging analog instruments, narrow-frequency bandwidths, and incompatible data types that made data exchange difficult. The inability of seismologists to explore deeper regions of the mantle beneath the continents at geologic scales with existing instrumentation precipitated a crisis in seismology, one that led to an innovative rethinking of the instrumentation and experimental design required to explore the deep lithosphere (e.g., Panel on Seismological Studies, 1984). Some of the pioneering efforts to implement portable arrays, for example, were motivated by the fact that 3-D imaging of surface waves across heterogeneous regions of continents thousands of kilometers in extent at geologically useful resolution requires relatively large numbers of closely spaced (100–200 km or better) instruments. One of the first portable seismic studies thus motivated was the Network of Autonomously Recording Seismography (NARS) project, a linear array of 16 long-period seismographs across western Europe for studying surface wave propagation (Nolet and Vlaar, 1981; Nolet et al., 1986). The successful NARS project, largely the work of Nolet and colleagues at Utrecht, was followed closely in time by a national effort within the US seismological research community to initiate a consortium program of portable array seismology for the study of the continental lithosphere. By 1984, the seismic community within the United States, through a series of workshops and scientific reports from the National Academy of Sciences, the National Science Foundation (NSF), and others, had defined broad goals for a new generation of seismic instrumentation, goals so ambitious in scope that they could be achieved only through the collective strength of a national seismology consortium. The formation in 1984 of the Incorporated Research Institutions for Seismology (IRIS) was a watershed event for seismology worldwide. By the mid-1980s, large-scale efforts were underway, not only within the United States but also elsewhere, to design and acquire large numbers of high-performance portable instruments that could be arrayed anywhere in the world for geologic-scale imaging of the deep underpinnings of continents (e.g., Aster et al., 2005). The IRIS initiative for portable seismology, formally termed the Program for Array Seismic Studies of the Continental Lithosphere (PASSCAL) and funded by the NSF, acquired several hundred standardized state-of-the-art portable seismic data loggers and sensors (broadband, intermediate period, and short period) over the next decades. This instrument pool is housed and maintained at a central PASSCAL instrumentation facility and is available to the scientific community for seismic research. IRIS also supports the GSN of about 140 permanent broadband stations worldwide, and both PASSCAL and GSN digital data are archived and provided to researchers worldwide through the IRIS Data Management Center (DMC). While parallel efforts to organize both instrumentation and data archiving have been undertaken elsewhere in the world and continue to grow in importance, IRIS/PASSCAL remains the dominant force behind portable broadband seismology around the globe. Major studies with PASSCAL instrumentation have been, and are being, carried out on every continent on the globe (**Figure 1**). As discussed near the end of this chapter, the scientific capabilities developed over the past 20 years as part of PASSCAL are today being leveraged to implement the EarthScope USArray program to image all of the continental United States.

The purpose of this chapter is to acquaint the nonspecialist with the current observational capabilities of portable array seismology, as well as with major findings that have emerged from large-scale portable, primarily broadband, experiments. The explosive growth of the literature pertaining to portable array seismology precludes a comprehensive review of results in the brief space allotted in this chapter. The sampling of portable array seismic experiments worldwide that are included here thus reflects the author's personal preference for which results have most impacted the science. As such, this chapter is intended to provide an abridged overview of passive array seismology's contribution to our knowledge of the deep velocity and discontinuity

structure of continental lithosphere and how that in turn has led to a better understanding of continental formation and evolution.

1.16.2 Natural Source Portable Array Seismology

Controlled-source seismic methods that utilize explosions or other artificial sound sources have proved to be very effective tools for exploring the Earth's crust in two and three dimensions. It is, however, a far more demanding task to probe the deep crust and upper mantle at anything approaching a similarly 'geologically meaningful' resolution. In fact, until the development in the last decade of portable digital broadband seismic systems with continuous high-fidelity recording capabilities and accurate absolute Global Positioning System (GPS) timing, high-resolution 3-D imaging of the continental mantle was essentially beyond the reach of seismology. The seismic sources for broadband array experiments are earthquakes of all kinds, from nearby local events to 'teleseismic' events at epicentral distances >27°; thus, broadband stations typically record continuously for up to 1–2 years. In broadband seismology (and most array seismology today), all three components of ground motion (vertical and two orthogonal horizontal directions, generally N–S and E–W) are recorded and the systems are capable of observing most of the radiated earthquake spectrum that is used for continent-scale seismic studies. Broadband seismic records, coupled with extremely accurate GPS clock timing, are the key ingredients for geologic-scale imaging of deep continental structure.

1.16.2.1 Instrumentation

The emergence of low-power portable broadband digital instrumentation represented a first-order revolution in seismology. For the first time, portable seismic instruments capable of recording data of near-observatory quality could be deployed anywhere in the world (Aster et al., 2005; Owens and Fowler, 2003). The circumstances that led to that revolution in seismic instrumentation and data quality were a combination of good timing and the formation of IRIS. Of vital importance was the rapid development of microprocessor technology for the emerging popular computer market. Thus, the design for versatile multichannel digital seismograph systems was leveraged from state-of-the-art digital technologies developed for computer and other mass consumer market applications. The following is a brief description of broadband instrumentation as it pertains to passive array studies of continental lithosphere.

The standard portable array seismic system today (2006) consists of a digital data logger and a seismometer (**Figure 2**), a GPS unit for both absolute timing and station location, a battery/solar panel power supply, and auxiliary devices and cables for connecting these units and communicating with them in the field. Photos of a typical field installation are shown in **Figure 2(c)**. The data loggers are low-power, high-dynamic-range (24-bit) microprocessor-based digital recording systems with several gigabytes or more of mass storage to allow continuous three-channel recording for months unattended. While digitizing rates of up to 1000 samples per second are attainable with current data loggers, sampling rates are typically around 40 samples per second, which is sufficient for all teleseismic recording and for most regional events. In addition to continuous recording, the data loggers can analyze incoming events in real time and activate 'triggers' to initiate higher sample rates to record over a specified time window according to the nature of the incoming seismic signal.

The portable broadband sensor, rugged, low-power, and simple to install, is the key component of continent-scale seismology. Broadband, high-dynamic-range units have been available since about 1990 with the production of advanced

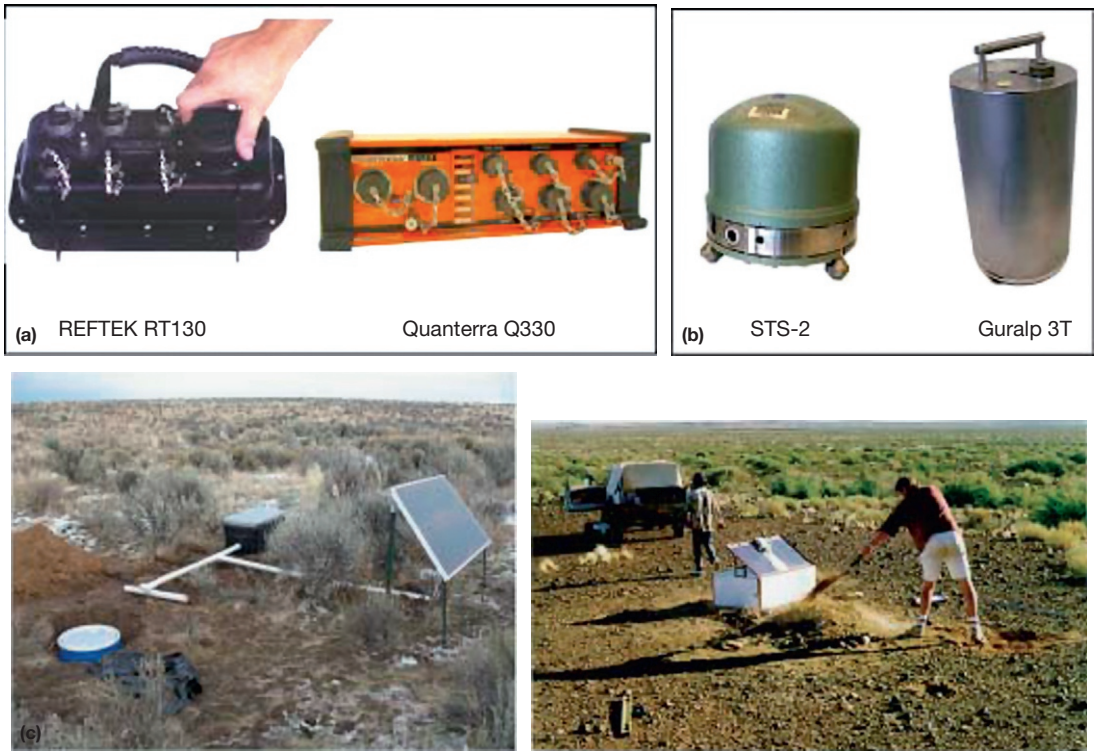

Figure 2 (a) Standard low-power (<1.0 W) 24-bit six-channel data loggers used in passive array experiments. The REFTEK RT-130 shown on the left can record at least three channels of data in several data streams of differing sample rates. The data logger uses GPS for absolute timing (generally to microsecond accuracy) and flash memory cards for mass storage. The Quanterra Q330 data logger shown on the right is specifically configured for real-time telemetry that includes duplex communication and burst or continuous transmission. (b) State-of-the-art force-feedback portable broadband sensors in general use today. Both units shown are low-power (<1.0 W), are capable of remote mass recentering, and have flat velocity-frequency response 50–0.008 Hz. On the left, the Streckeisen STS-2 is manufactured in Switzerland, weighs about 9 kg, and is 23 cm high. On the right, the Guralp CMG-3T, manufactured in England, weighs 14 kg and stands 38 cm high. (c) Typical portable field installations. Left: basic broadband station layout at a High Lava Plains (HLP) site in eastern Oregon. Sensor vault consists of a 30 gallon (blue) plastic drum in which the sensor is placed on a concrete base, oriented and leveled, and thermally insulated. A watertight enclosure houses the data logger, powerbox, and batteries. Wiring between sensor and data logger and power sources is through PVC conduit. The station shown is powered by a single 60 W solar panel and two deep-cycle marine batteries intended to last the full 2-year life of the installation. Right: broadband station for the southern African (Kaapvaal) experiment. Vault is covered with insulating dirt to a depth of at least 30–40 cm. Solar panels and GPS unit are mounted on the roof of a 'doghouse' wherein the data logger and auxiliary electronics are housed.

broadband systems by Streckeisen in Switzerland and Guralp in England (Figure 2(b)). All portable broadband seismometers in use today operate on the principle of a negative feedback loop that is applied to a small inertial mass to hold it fixed relative to the moving seismometer reference frame. The amount of electromotive force that is applied to keep the mass in place is used to measure ground acceleration. Because the mass moves very slightly (ideally, not at all), the force-feedback system has much better linearity and significantly expanded frequency range relative to mechanical seismometers (see, e.g., Lay and Wallace, 1995; Wielandt and Streckeisen, 1982, for further discussion). Compact low-power electronic force-feedback systems can thus be configured for a very wide range of seismometer responses: the state-of-the-art Streckeisen STS-2 and Guralp CMG-3T portable sensors, for example, have a flat velocity response from about 50 to 0.008 Hz, sufficient to cover virtually all of the body wave and surface wave bandwidth of interest for lithospheric studies.

Much of the imaging of the deep continents (see Section 1.16.2.4) that is done with portable arrays depends on precise absolute timing made possible for the first time worldwide by the US Department of Defense launch of the GPS in the 1990s. GPS satellites transmit signals that contain extremely accurate time codes, as well as information that allows a GPS receiver on the Earth's surface to compute its position to within a few meters anywhere on the globe. The accurate time signals, recorded independently at each seismic station, allow seismic signals across an entire array of stations, each with independent timing, to be correlated to hundredths or even thousandths of a second, making it possible to quantify travel-time differences between stations at very high accuracy. The availability of matched broadband stations that operate with an extremely accurate common time base is the critical factor that has made high-resolution tomographic imaging of the continental lithosphere a reality.

Real-time telemetry, both radio and satellite, has evolved slowly since the late 1980s when the first very low-bandwidth satellite transmission systems were deployed (e.g., Poupinet et al., 1989a,b). While progress, particularly in satellite communication, has been surprisingly sporadic, telemetry has

played an increasing role in passive array seismology in the last decade. Systems that transmit data to a central collection site in approximately real time have proved to significantly improve both quality control and data recovery. Although the most commonly used systems to date are still those that employ line-of-sight radios (e.g., the PASSCAL 32-station broadband telemetering system), satellite and cellular communications are increasingly feasible, both technically and economically. Data from many of the USArray stations (see **Section 1.16.7**) are transmitted via satellite.

1.16.2.2 Portable Array Experiments

Natural source portable array experiments have been carried out in every continent. **Figure 1** shows PASSCAL deployments over just the 5-year period 2000–05. In addition to the PASSCAL experiments shown in **Figure 1**, substantial numbers of other portable seismic experiments have been carried out in recent years by other international research groups. (Space limitations confine the scope of this chapter to portable array studies of continental regions. Unfortunately, this excludes even mature island arcs, notably Japan, where dense networks of advanced permanent seismic stations blanket the islands. A satisfactory summary of the many fine studies of subduction zone structure beneath Japan based on data from the permanent networks is beyond the bounds of this work.) While local and regional events are commonly incorporated in portable array experiments, nearly all broadband imaging depends heavily on teleseismic events, epicentral distances $>27°$. Station arrays are designed according to the nature of the scientific target(s), the methodologies to be used, the number and type of the instruments available for the experiment, and the distribution of teleseismic sources. In general, arrays tend to be deployed either along 1-D transects or in a 2-D grid. Station density is typically constrained by the number of instruments: where ample instrumentation is available, interstation spacing of about 10 km is sufficient for unaliased imaging at dominant teleseismic wave frequencies, where maximum P-wave energy tends to be concentrated around 1 Hz (e.g., Levander, 2003). Nonetheless, a number of portable broadband experiments have deployed instruments along profiles at even denser intervals, where the objective was to image crustal and upper-mantle discontinuities across complex geologic terranes. Examples include Nabelek et al. (1993), $\sim$5 km spacing along a linear profile across the Oregon Cascades, and Zhao et al. (2001), $\sim$5–10 km along the INDEPTH III transect in central Tibet. A few passive array experiments, most with the objective of imaging very shallow structures, may have instrument spacing as close as 1 km (e.g., Roecker et al., 2004; Thurber et al., 2004). Where the targets are deep crustal or mantle structures, however, even very ambitious projects more commonly involve interstation spacing around 20 km (e.g., Wilson and Aster, 2003; the La RISTRA profile in the western United States, with station spacing of about 18 km along a 950 km transect). In almost every case, primarily because of limitations in the numbers of instruments, dense deployments are more commonly seen in linear transects and the resulting analysis 2-D rather than 3-D. Where the scientific objective is 3-D imaging of larger regions encompassing multiple terranes, deployments tend to be more widely spaced, either in a grid or on a long profile, and interstation distances may be 50–100 km. Typical of a gridded experiment of this type is the southern African seismic experiment (e.g., James, 2003) where station spacing was on the order of 100 km and array dimensions about 1800×600 km.

1.16.2.3 Field Installations and Data Acquisition

A typical portable broadband installation is effectively a semipermanent miniobservatory. As such, its functional capabilities approach those of a state-of-the-art global seismic station and, because it can be sited in remote locations with little cultural noise, may even be superior in performance. While relatively few studies have sought to define optimum vault design for broadband installations (e.g., de la Torre and Sheehan, 2005), the primary keys to achieving low noise include thermal stability, proximity to bedrock, and absence of cultural noise. Photos of a typical portable station installation are shown in **Figure 2(c)**. While no absolute standards have been adopted for the construction of a portable broadband station, a number of features are common to virtually all installations. As shown in **Figure 2(c)**, the three-component broadband sensor is installed below ground in a constant temperature 'vault,' typically constructed from a plastic or steel drum. A thin concrete layer, laid down to provide a level surface for sensor installation, is poured atop bedrock at the bottom of the hole. When steel drums are used for the vault, it is common to remove the base of the drum and to isolate the drum walls from the concrete pad. Where plastic drums are used, the bottom of the drum may be left intact, worked into the concrete layer atop bedrock, and then filled with an additional several centimeters of concrete as a base pad for the sensor. The sensor pad, ideally bonded to bedrock, is typically some 40–70 cm beneath ground level. The sensor is leveled and the horizontal components oriented precisely. Cables are connected via PVC pipe (see **Figure 2(c)**). A close-fitting Styrofoam housing and other insulation are placed over the sensor and within the drum to minimize thermally induced air circulation that will adversely affect sensor stability. After the sensor has been installed, the lid of the vault is sealed and the whole assembly is buried in insulating dirt to a depth of at least 50 cm. Under normal operations, the sensor vault will remain sealed until the end of the deployment. A typical station is powered by one or two standard marine deep-cycle batteries that are kept charged by solar panels. Months of seismic data, typically sampled at a rate of 20–40 samples per second, can be stored on several gigabytes of disk or flash memory. A small external GPS antenna is mounted with an unobstructed view of the sky. Routine station servicing, typically at 3–6-month intervals, consists primarily of checking that data recording is normal and the GPS clock is operating correctly, swapping out data memory cards and calibrating the sensor. Where telemetered, cellular, or satellite communication has been implemented, stations may need no on-site servicing at all. For PASSCAL experiments, data collected at each station are generally returned to a local operations center where they are copied, preprocessed into a standard database, and transmitted to the IRIS DMC for permanent data archiving.

1.16.2.4 Methods of Analysis

The dramatic increase in the volume of high-quality portable broadband data has spurred the development of advanced

imaging tools to capitalize on those data, and a vast literature has developed on the subject in just the past few years (e.g., Levander, 2003; Levander and Nolet, 2005; Pavlis, 2003; Sheehan et al., 2000; Wilson and Aster, 2005). The brief nontechnical summary of methodologies presented later in the text touches on some of the more common methods in use today, but for more comprehensive treatment, the reader is referred to **Chapters 1.08** and **1.10** in this volume and to the literature cited here.

Part of the sea change brought about by increasingly large-scale deployments of broadband instruments is the development of (1) tomographic methods to image geologically identifiable features in the mantle and (2) advanced methods for direct waveform imaging of crust and mantle discontinuities similar in style to that used in seismic exploration (e.g., Pavlis, 2003). Two basic categories underpin most of the imaging that is done with portable arrays. The first may be termed 'volumetric' imaging, the most important class of which is tomography, both body wave and surface wave, although it also includes attenuation tomography and mantle anisotropy. High-resolution tomography demands quality seismograms from high-performance standardized instrumentation, with high-fidelity waveforms and very accurate absolute timing. These requirements have only recently been realized, so that as the quality and quantity of data have improved, tomographic imaging has become one of the most powerful tools seismologists have to study the deep continental lithosphere.

'Discontinuity,' or scattering, imaging is complementary to tomographic imaging and is aimed at direct imaging of subsurface discontinuity structure (scatterers) in both two and three dimensions. All discontinuity imaging is based on the interpretation of scattered energy in the seismogram, that is, the conversions and reflections of P and S waves at velocity discontinuities in the Earth where rock types or material properties of the rocks change significantly over relatively short-distance scales. As the station spacing of portable arrays has densified, analytic methods developed for seismic reflection imaging by the exploration industry have become increasingly applicable (e.g., Levander, 2003; Pavlis, 2003; Rondenay et al., 2005). Continuous unaliased high-resolution images in 2-D are now relatively common, and continuous 3-D imaging has been experimented with in several recent portable array studies.

1.16.2.4.1 Body wave tomography

Except where high levels of earthquake activity are in the same geographic region of interest as the observing stations, body wave tomography of structure beneath a network of portable stations is generally based on teleseismic relative arrival times measured across the array (e.g., Nolet, 1987; VanDecar, 1991). The marked improvement in the reliability and resolving capability of portable array body wave tomography over the past decade owes partly to much advanced methods of analysis, but more to greatly enhanced quantity and quality of the data. As relative arrival times are the primary input data for regional tomographic modeling, the term 'quality of data' refers primarily to clock reliability, signal-to-noise ratio, and waveform fidelity: whatever the specific tomographic computational methods adopted, the quality of the results hinges on these factors. To remove the complicating effects of heterogeneous upper-mantle structure in the tomographic analysis, earthquake data are typically confined to events beyond about 27° distance, where seismic waves bottom in the relatively uncomplicated lower mantle below the upper-mantle transition zone (between 410 and 660 km). Tomographic analysis takes as its input the relative travel-time residuals across the array relative to a spherical reference Earth model. These residuals are the data that are then inverted to obtain 3-D velocity variations beneath the array of stations (see **Chapter 1.10**).

In studies prior to about 1990, it was common to obtain travel-time residuals from handpicked absolute arrival times. That method may still be used for seismic networks that cover large geographic areas and/or that involve a mix of instrument types where waveform correlations are difficult. In these instances, the absolute travel time of the seismic wave between earthquake source and receiver is referenced to a standard Earth model. For portable array tomography, where the structure of interest lies beneath the station network, relative residuals (delay times) are computed for each observed travel time by subtracting the mean of the absolute travel-time residuals for each event (relative to the standard model) from the observed travel time for that event at each station. The data are time-shifted so that the mean of the travel-time residuals for each event is zero. This process of obtaining relative travel-time residuals significantly reduces the influence of extraneous factors, such as errors in event location or origin time, deep-mantle velocity anomalies, and an inaccurate reference model that can introduce very substantial errors in regional tomographic models (e.g., VanDecar, 1991; Humphreys and Dueker, 1994). VanDecar and Crosson (1990) introduced the now common method of using pairwise cross correlation to align waveforms more precisely and obtain a statistically optimized set of relative arrival times. Tomographic inversion of the relative travel-time data to obtain a seismic velocity model involves partitioning the volume of interest beneath the array into a 3-D grid of blocks or knots. The relative travel-time residuals from many hundreds or thousands of crisscrossing rays through the volume beneath the array are inverted to obtain a least-squares estimate of the relative velocities within each block. The density of crossing rays is a critical factor in the ability of the tomographic inversion to resolve structure, which thus depends on earthquake sources that are well distributed in both azimuth and distance (see **Chapter 1.10**). By the VanDecar method of tomographic analysis (e.g., VanDecar, 1991; VanDecar et al., 1995), the data are inverted simultaneously for the velocity structure, earthquake relocations, and station corrections. As the least-squares solution is not unique, the inversion searches for the simplest model that contains the 'least' amount of structure required to satisfy the observations.

1.16.2.4.2 Surface wave tomography

Surface waves observed in the Earth are dispersive (see **Chapters 1.03** and **1.08**). That dispersion is caused by the fact that higher frequencies are sensitive to shallow structures and lower frequencies to deeper structure such that different frequencies travel with different velocities. While surface waves have been used to sample shear-wave velocities to depths of 1000 km or more in global studies, the maximum depths that can be resolved from portable array data are rarely more than a few hundred kilometers.

A number of different methods of surface wave tomography have been developed, although the most common for studying continental lithosphere fall into two general categories: (1) partitioned waveform inversion (PWI), where surface waveforms (including S and multiple S) are modeled directly, and (2) a variety of methods that require direct measurement of phase velocities across the array. Significant advances in crustal imaging have also been made using portable array data, including higher-mode group velocity tomography (Levshin et al., 2005) and ambient noise tomography (Shapiro et al., 2005).

PWI, first applied for 2-D structures to the linear NARSs, is a two-step process (Nolet, 1990). The first step involves nonlinear waveform fitting of fundamental and higher-mode surface waves where the S wave, multiple S wave, and surface wave train of the time series are matched by synthetic seismograms to obtain a path-average 1-D velocity model representing the average Earth structure between source and receiver. The synthetic seismograms that are used to fit the observed data can be computed by different methods. While all these methods require information on the focal mechanism of the earthquake source, no direct measurement of group or phase velocities is involved. Once the path-averaged 1-D structures are obtained for all source–receiver pairs, a generalized least-squares tomographic inversion, similar to that for body wave inversion, is performed to obtain the 3-D (or 2-D, in the case of linear transects) shear-wave speed beneath the array. Crustal thickness may be constrained or it may be included in the inversion. PWI, or some variant of it (e.g., Friederich, 2003), has been widely used for continent-scale studies (e.g., Friederich, 2003; Simons et al., 1999; Van der Lee and Nolet, 1997; van der Lee et al., 2001a), but has relatively limited application to smaller regional arrays where more array-specific techniques can be applied.

Array techniques, based largely on Rayleigh wave data recorded on local or regional seismic networks, have evolved substantially in the past decade as broadband arrays have increased in areal extent and station density. The simplest of these, and still one of the more robust, involves determining phase velocity between station pairs aligned on the great circle path with the earthquake (e.g., Larson et al., 2006; Snoke and James, 1997). More sophisticated array methods in use today attempt to account for multipathing and other out-of-plane propagation. One means to accomplish this is by representing the incoming wavefield as a superposition of two interfering plane waves whose parameters (amplitude, phase, and direction) are determined in the inversion (e.g., Bruneton et al., 2004; Forsyth and Li, 2005; Li et al., 2005). This and similar methods can also include an estimate of azimuthal anisotropy (Forsyth and Li, 2005). Where Rayleigh wave, Love wave, and multiple S-wave data are available, Gee and Jordan (1992) developed an isolation filter technique to determine radial anisotropy, as well as phase delays across the array (see also Freybourger et al., 2001; Saltzer, 2002).

Recent forays into the joint inversion of surface waves and body waves from portable arrays (e.g., Friederich, 2003; van der Lee et al., 2001b; West et al., 2004a) are mostly in an embryonic stage but hold promise of major improvements in imaging with further development. Much of the motivation for joint inversion derives from two factors. First, surface waves provide good vertical resolution (but poor lateral resolution), while body waves provide excellent lateral resolution (but poor vertical resolution) of the 3-D velocity structure. Jointly, they thus provide complementary constraints on the velocity structure both laterally and vertically across the array. Second, the inclusion of surface wave data in the inversion makes it possible to attach absolute S-wave velocities to what are otherwise simply velocity perturbations in the body wave inversion alone. The technique developed by West et al. (2004a) treats the surface wave measurements simply as travel times between stations, with each travel time corresponding to a horizontally traveling ray through the blocks in the model. The horizontally traveling surface wave rays are sensitive over a depth range estimated for each given frequency but otherwise can be added directly as an additional set of ray paths to the body wave data.

1.16.2.4.3 Discontinuity imaging

Most direct imaging of discontinuity structure is based on some version of teleseismic receiver function analysis, although full-scattering formulations are increasingly evident (e.g., Rondenay et al. (2005), with references). Receiver functions are computed primarily for teleseismic events (30–90° epicentral distance), where incoming P-rays beneath the station are at near-vertical incidence. The near-vertically propagating P wave that is incident on a horizontal boundary across which there is a significant contrast in V_s will convert a small amount of its energy to an S wave. The particle motion of the resulting P-to-S conversion will be predominantly horizontal radial and thus recorded primarily on the radial component of the seismogram (**Figure 3(a)**). Nonhorizontal discontinuities can produce significant P-to-S-converted energy on the transverse component, as may anisotropy in some cases. While these effects are typically small, inspection of the transverse component will reveal whether such factors are important.

All of the converted signals are of small amplitude and tend to be concealed in the coda of much larger amplitude direct-arriving P waves. The receiver function is a means of isolating these relatively small amplitude P-to-S (Ps) conversions that are produced beneath the station from the much larger amplitude direct P-wave arrivals that dominate the same early portion of the record (also see **Chapter 1.21** for further discussion). To compute the receiver function, the vertical component signal (which nominally contains only P-wave energy) is deconvolved from the radial component (which contains both P-wave energy and S-wave energy) to produce a so-called 'source-equalized' radial seismogram (e.g., Ammon, 1991). Under ideal conditions, the source-equalized (deconvolved) trace consists of a large amplitude coherence spike at zero time (containing all the P-wave energy present on the original radial component that is coherent with the vertical component) and a following spike train of smaller signals that are the Ps conversions and converted reflections from discontinuities beneath the station (**Figure 3(a)**). Thus, the receiver function can be considered a scaled version of the radial component of displacement with the P-wave train removed (Ammon, 1991); also see Wilson and Aster (2005)). The receiver function may be used to image any discontinuity at depth but, in practice, has been used primarily for imaging the Moho, the top of the descending plate in subduction zones,

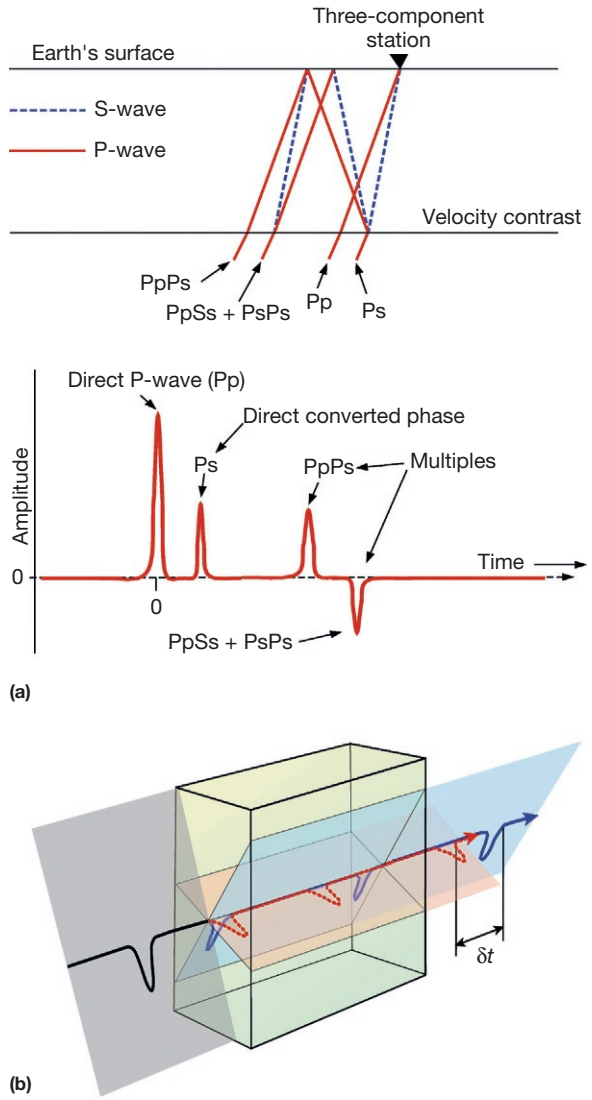

Figure 3 (a) Basic ray geometry and radial receiver function diagram for a simple one-layer model over a half-space, with a velocity discontinuity in S. Ray nomenclature is as diagramed on the upper figure. The receiver function is obtained by deconvolving the vertical component record from the radial component. The coherence peak of 'all' direct P-wave energy arriving at the station within the time window of the deconvolution trace is labeled 'direct P wave.' High-quality converted wave signals can be obtained by deconvolution even in cases where the source-time function of the earthquake may be quite lengthy and complex and individual signals extremely difficult to detect. The amplitude of the P-to-S conversion is a function primarily of the S-wave velocity contrast across the boundary. Figure courtesy of Rick Aster, New Mexico Tech. (b) Schematic diagram showing the effects of anisotropy on a seismic wave passing through an anisotropic medium. In this case, the incident wave is a polarized shear wave (such as the core phase SKS). On passing through the anisotropic medium (anisotropy is indicated by different colored planes within the volume shown), the wave 'splits' into a fast and a slow component ('shear-wave splitting'). The magnitude of the lapse time, δt, between fast and slow shear-wave components is a function of both the path length and the strength of the anisotropy. If the incident wave is polarized parallel to one of the axes of anisotropy, no S-wave splitting will occur. Figure courtesy of Ed Garnero, Arizona State University.

and upper-mantle discontinuities including the 410 and 660 km discontinuities.

Sp receiver functions. Receiver functions based on P-to-S conversions have proved to be remarkably effective for imaging the Moho and the 410 and 660 km discontinuities of the transition zone. Because of the interfering effects of crustal multiples, however, these receiver functions have proved to be difficult to interpret unambiguously for upper-mantle structures in the depth range 100–300 km. Several recent papers have addressed that problem by examining S-to-P conversions, where the primary conversions precede the S-wave arrival and all multiples are in the S coda (Farra and Vinnik, 2000; Wittlinger et al., 2004). The method for computing Sp receiver functions was first formalized by Farra and Vinnik (2000), where the vertical component is deconvolved by the radial, similar to that of the Ps receiver function but where the respective roles of P and Sv are reversed. The method tends to be limited by the fact that earthquake magnitudes must be substantially larger than for Ps receiver functions and piercing (conversion) points are substantially further from the station as the S-to-P conversion results in a much lower-angle incident ray.

1.16.2.4.4 Anisotropy

Seismic anisotropy, or seismic birefringence, is a key measurement for imaging past and present deformation in the Earth's interior (see Fouch and Rondenay (2006) for a comprehensive summary). Thousands of shear-wave (radially polarized core phases SKS and SKKS) splitting measurements over the past two decades have shown that anisotropy in the upper mantle is present almost everywhere, both on and off continents. Splitting measurements are especially applicable to the upper mantle and, to a lesser extent, the crust, where tectonic and flow deformation results in anisotropic fabric through crystallographic alignment of anisotropic minerals. In the case of portable array experiments, attention has focused primarily on the upper mantle, where seismic anisotropy is generally interpreted in terms of lattice-preferred orientation of olivine, which deforms under stress to produce strongly anisotropic strain-induced fabric. Vinnik et al. (1984) first recognized that the radially polarized Sv waveforms of SKS and SKKS core phases could be used to obtain extremely simple *in situ* measurements of azimuthal (horizontal plane) S-wave anisotropy (**Figure 3(b)**). The method has since been refined (Silver and Chan, 1988) and routinely used to determine anisotropic fast directions and delay times for virtually every station in nearly every passive array deployment since (see summaries in Fouch and Rondenay, 2006; Silver, 1996). Surface wave anisotropy can be either radial (vertical) or azimuthal (horizontal). Radial anisotropy, which cannot be observed by shear-wave splitting, is manifest as model incompatibility between Rayleigh waves and Love waves. In such cases, Love waves invariably call for a substantially higher S-wave velocity structure than do the Rayleigh waves, and in those anisotropic models, the difference between the so-called V_{SH} structure and V_{SV} structure is commonly quite large, with V_{SH} the higher velocity. Azimuthal anisotropy, on the other hand, is difficult to determine by surface waves alone and requires multiple measurements along many azimuths across the array (e.g.,

Forsyth and Li, 2005). While lateral resolution in all surface wave methods is relatively poor, a major strength of surface wave anisotropy, both radial and azimuthal, is the relatively good depth resolution. This overcomes one of the great weaknesses of shear-wave splitting methods where depth of the anisotropy cannot be determined, and it is for this reason that the joint use of surface waves and core phases is coming increasingly into play (e.g., Gaherty, 2004).

Anisotropy takes a back seat to tomographic and waveform imaging in the sections that follow. Not only is this partly the personal preference of the author, but also it is a consequence of the fact that anisotropy as it relates directly to structure of the continental lithosphere (fossil anisotropy) is commonly difficult to sort out from asthenospheric flow. The interested reader is referred to Fouch and Rondenay (2006) and Silver (1996) for further enlightenment.

1.16.2.5 Methodological Weaknesses and Caveats

The previously mentioned description of methods has necessarily been brief. It is particularly useful, therefore, to highlight pitfalls in some of the various techniques in common usage today.

Seismic tomography. The rapid increase in the number and density of instruments comprising seismic arrays has led to increasingly high-resolution tomographic images that appear to be interpretable in geologic or near-geologic terms. The tomographic problem is underdetermined, however, which means that all 3-D tomographic images are smoothed and damped to a greater or lesser degree and all are nonunique. Indeed, even the best-constrained models are blurred images of the actual structure, smoothed across small-scale heterogeneities. Moreover, unlike the medical CT scan, a major shortcoming in seismic tomography is the uneven distribution of sources (and often receivers), such that some parts of the region to be imaged are better constrained by data than others. In addition, as stations are always at or near the Earth's surface, seismic rays pass through the volume to be imaged in only one direction, from below. Where stations are arrayed along 1-D profiles, the uncertainties in the resulting 2-D solution can be substantially greater than they are for comparable 3-D solutions from areal deployments.

Apart from the problem of image smearing and nonuniqueness, body wave inversions are nearly always expressed in terms of velocity 'perturbations,' or velocities relative to the mean velocity over the model space ('not' relative to the background starting model). In regions of overall high velocity or low velocity, relative velocity images can be misleading. A significant advantage of surface wave imaging is that absolute velocities are determined. Body wave tomographic velocity perturbations tend to smear along ray paths, such that those images provide generally good constraints on lateral heterogeneity but poor control on vertical structure. Similarly, surface wave tomography provides good control on vertical structure, but poor control on lateral structure. This is a primary motivation for joint body wave/surface wave inversion where both lateral and vertical structures can be better constrained. In all cases, the color scheme used by the author to signify velocity contrast can have a major effect on the appearance of the image. The reader is invited to examine some of the images in this chapter to see whether it is possible to spot such effects.

Receiver function methods. Receiver functions are most easily interpreted when relatively sharp subhorizontal boundaries with strong S-wave contrasts are present. Dense arrays allow powerful exploration-type analyses to be applied to the data to obtain 2-D or 3-D images of crustal and mantle discontinuities. Shortcomings of standard receiver function methods (as opposed to full wavefield scattering methods) include difficulty in accommodating anisotropy, dipping layers, reverberations between layers, gradational variations in structure, and distant scattering (e.g., core reflections). Running averages over arrays of stations can make structures appear to be far more continuous than the individual station data suggest (e.g., Yuan et al., 2000). While various techniques have been, or are being, developed to deal with the many known shortcomings, receiver function images are commonly degraded by one or more of these effects. Crustal reverberations, for example, make Ps receiver function images unreliable in the depth range 100–200 km. Anisotropy and dipping layers must be evaluated through an examination of energy on the transverse component, but this precaution is commonly ignored.

Anisotropy. The determination of shear-wave (SKS) splitting is among the simplest of all processing procedures in seismology, readily accessible through publicly available 'canned' codes, and is hence fraught with pitfalls. First, the magnitude of azimuthal anisotropy as a function of depth cannot be determined from SKS splitting alone, nor can the cause of the anisotropy itself. Interpretations based on simplifying assumptions of uniform single-layer anisotropy can be wildly misleading. Anisotropy observed through SKS splitting could originate anywhere along the path between the core–mantle boundary and the recording station. Substantial evidence exists that the lowermost mantle may be anisotropic as may be other parts of the lower mantle or transition zone (e.g., Fouch et al., 2001). It is known that SKS and SKKS can give wholly different splitting results, even when well observed on the same seismogram for the same event (e.g., James and Assumpção, 1996). Complexities such as multiple layers with differing anisotropies, dipping layers, and differing mineral anisotropies within a single layer all require data from well-distributed earthquake sources and comparatively sophisticated analysis to sort out. Radial anisotropy as manifested by a significant discrepancy between Rayleigh wave and Love wave S-wave velocity depth models can be relatively well constrained by depth, but lateral resolution of the anisotropy tends to be poor. Similarly, azimuthal anisotropy obtained from the analysis of fundamental-mode Rayleigh waves is well constrained vertically, but poorly constrained laterally.

1.16.3 Seismic Structure of Tectonically Active Regions

This section and the ones that follow are intended to provide the reader with a thumbnail sketch of some of representative findings from portable array (primarily broadband) seismology. Beginning with tectonically active regions, most portable array studies have focused on four major tectonic regimes: (1) western United States, where a complex series of events broadly associated with the Laramide orogeny and the overriding

of the Farallon spreading center have overprinted much of the Archean and Proterozoic lithosphere of western North America; (2) continent–continent collisional zones, notably the Himalayan/Tibetan orogenic belt; (3) intraplate rift zones, with perhaps the best example in northern Africa; and (4) continental margin subduction zones. In the following sections, we summarize representative results from each of these regions.

1.16.3.1 Western North America

The Rocky Mountain Front marks a profound divide between stable North America to the east and tectonically active North America on the west. Western United States is one of the most complex and most seismically investigated tectonic regions in the world. The tectonic provinces that make up the region record a baffling sequence of overlapping tectonomagmatic events dating from the Mesozoic to the present. These events appear to overprint and, in some cases, be controlled by the Archean and Proterozoic continental structures that comprise the deep framework of western North America. Over the past 70 My or so, western United States has undergone a succession of continent-shaping events – Farallon Plate subduction and destruction, extensional and compressional deformation, and tectonomagmatic activity – that continue to this day. During the past 30 My, most of the interior of western United States has seen tectonic extension. Portable array seismology has played a key role in unraveling the complex history of lithospheric evolution of the western United States, from early Proterozoic (~1.8 Ga), to the Laramide orogeny (~80–50 Ma), to Neogene tectonism that continues to the recent time.

Major geologic provinces of western United States are shown in Figure 4 superimposed on a composite image of upper-mantle S-wave velocity structure at 100 km depth

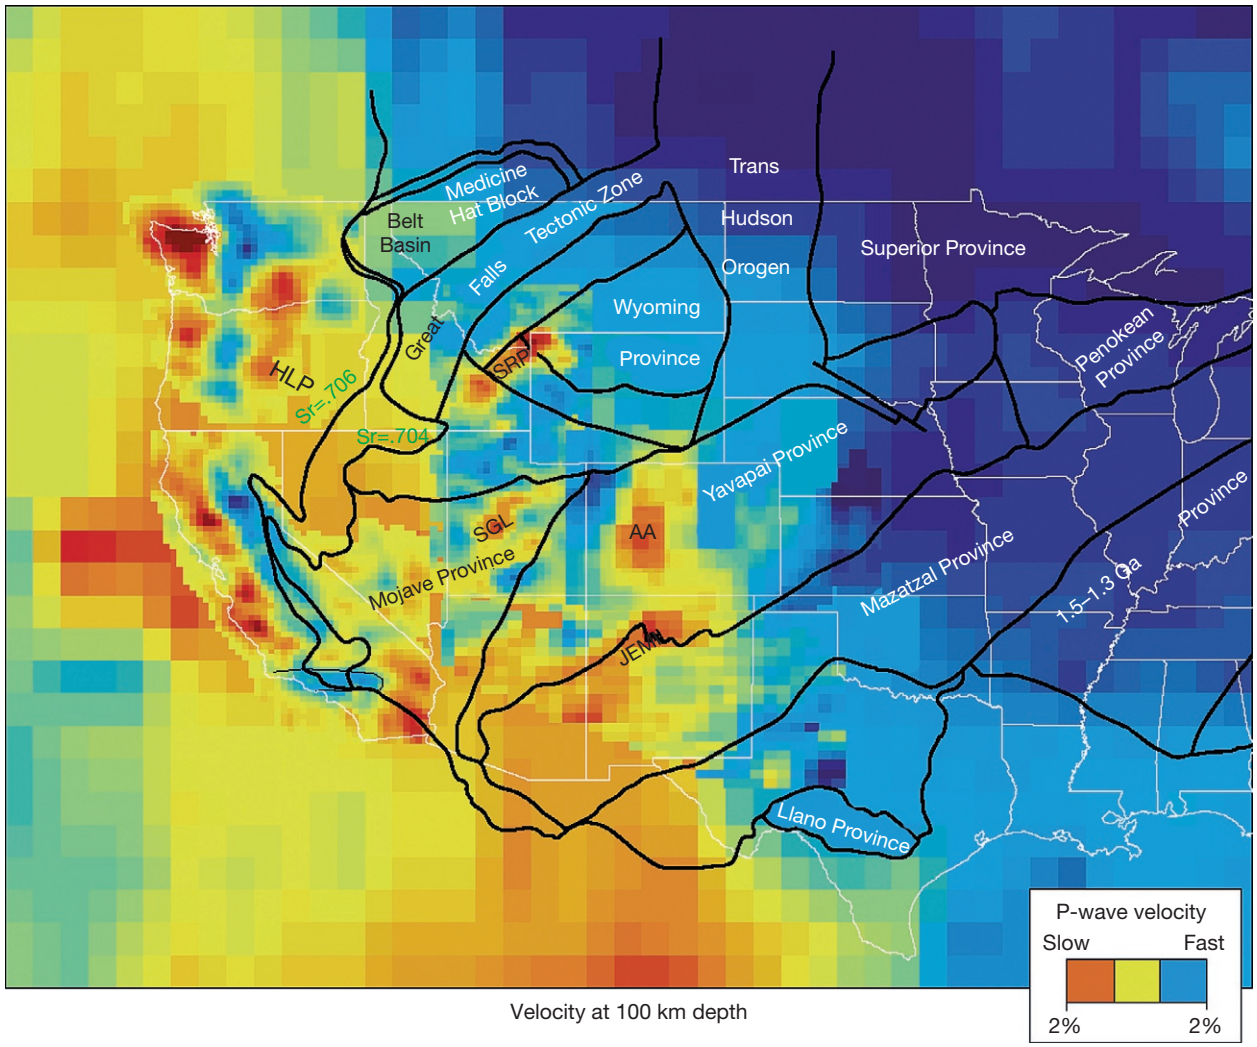

Figure 4 North American upper-mantle velocity perturbations at 100 km depth. Modified from Karlstrom KE and Keller GR (2005) *Geophysical Monograph 15: The Rocky Mountain Region – An Evolving Lithosphere: Tectonics, Geochemistry, and Geophysics*, 441 pp. Washington, DC: American Geophysical Union. The background continent-scale S-wave velocity perturbation structure is from Grand (1994), overlain by regional array P-wave velocity perturbations from Humphreys and Dueker (1994). Blue indicates positive (high) relative velocity; red indicates negative (low) relative velocity. Precambrian province boundaries are outlined in black. SRP, Snake River Plain; SGL, Saint George lineament; AA, Aspen anomaly; JEML, Jemez Lineament; HLP, High Lava Plains.

(Grand, 1994; Humphreys and Dueker, 1994). Extensive studies of this entire region of western United States are ongoing and expanding in scope (see **Section 1.16.7**). Nonetheless, it is useful to summarize some of the major syntheses and interpretations that have emerged from current studies of this actively evolving region. A considerable body of work is published in book form on the lithospheric and sublithospheric structure of the Rocky Mountain region from Montana south to New Mexico and west to the Basin and Range Province (Karlstrom and Keller, 2005), gleaned from the large-scale CD-ROM, La RISTRA, and Snake River Plain and Deep Probe teleseismic profiles (**Figure 5**; Karlstrom et al., 2005).

The tectonics of the Rocky Mountain region are dominated by NE–SW trending lineaments that mark zones of low-velocity mantle and extensive tectonomagmatic activity subparallel to Proterozoic province boundaries and to the direction of absolute plate motion of North America. As Karlstrom et al. (2005) pointed out, the S-wave velocity contrasts in the upper mantle over distances of less than 100 km can be as large as 10–15%, values that are comparable to continent-scale variations. If the velocity contrasts are interpreted as purely thermal, they imply temperature differences up to 700°, from shield-like geotherms to mantle undergoing partial melting. The sections that follow are organized such that the discussion begins with the Snake River Plain/Yellowstone region of the northern Rockies, moving to the southern Rockies near the eastern front with the Great Plains and then westward through the Colorado Plateau, the Basin and Range Province, northern Great Basin, and into the Sierra Nevada. Discussion of the active Cascade Arc is reserved for the sections in the succeeding text on continental margin subduction zones.

1.16.3.1.1 Snake River Plain/Yellowstone and Wyoming Craton

The Snake River Plain/Yellowstone (SRP/YS) region is among the most intensively studied in the world, with well over 100 broadband stations deployed regionally in several major experiments (Dueker and Yuan, 2004; Yuan and Dueker, 2005a). In addition to a large network of short-period and permanent stations that the University of Utah and US Geological Survey have maintained in the Yellowstone region for many years, several major PASSCAL deployments, all of a year or less, have added substantially to the database across the larger penumbra of the Yellowstone signature. The major issue surrounding the SRP/YS structure is whether it has been caused by

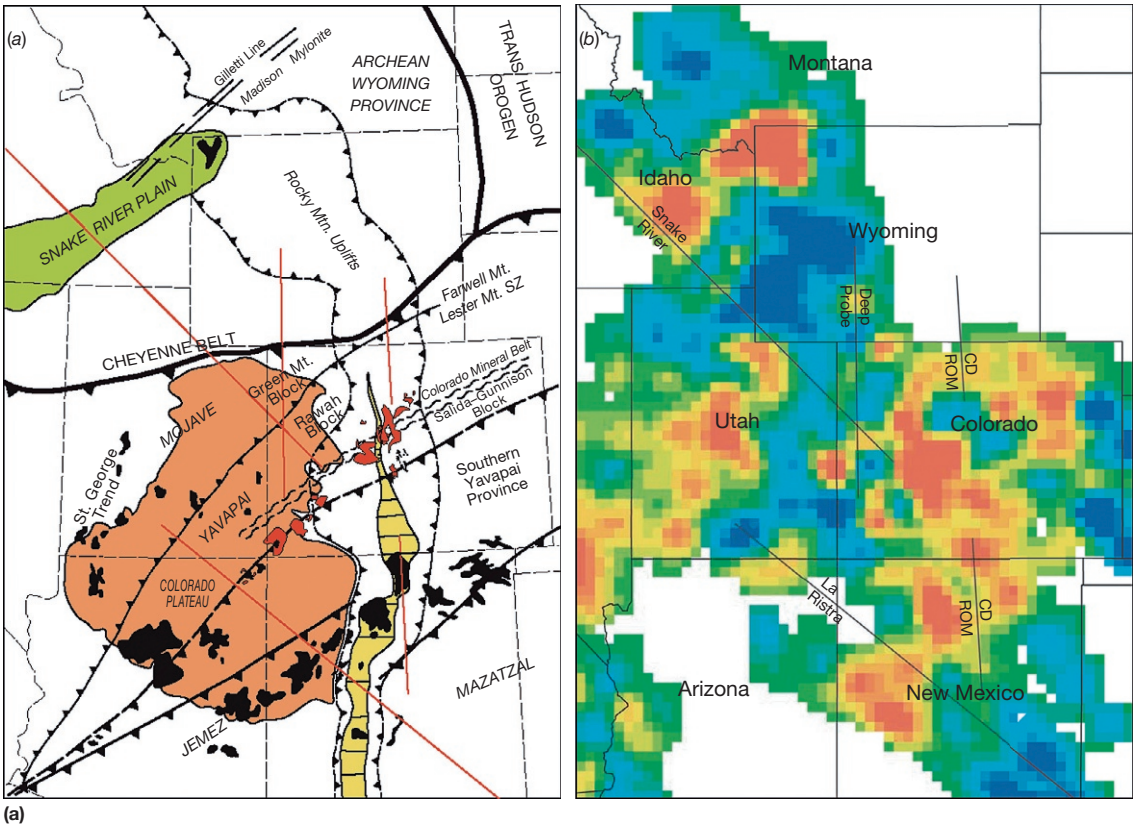

Figure 5 (a) Geologic elements (*a*) and tomographic image (*b*) of western United States west of the Rocky Mountain Front. Reproduced from Karlstrom KE, Whitmeyer SJ, Dueker KG, et al. (2005) Synthesis of results from the CD-ROM experiment: 4-D image of the lithosphere beneath the Rocky Mountains and implications for understanding the evolution of continental lithosphere. In: Karlstrom KE and Kelle GR (eds.) *The Rocky Mountain Region: An Evolving Lithosphere*, pp. 421–434. Washington, DC: American Geophysical Union. (a) Cenozoic volcanic fields (black and red areas) strike NE, roughly parallel to Precambrian trends, whereas Laramide uplifts trend N–S. (b) Locations of seismic transects that are shown as vertical sections in **Figure 10(b)** are superimposed on 100 km depth tomographic image. Blue indicates positive velocity perturbations; red, low-velocity perturbations.

(2005) Synthesis of results from the CD-ROM experiment: 4-D image of the lithosphere beneath the Rocky Mountains and implications for understanding the evolution of continental lithosphere. In: Karlstrom KE and Kelle GR (eds.) *The Rocky Mountain Region: An Evolving Lithosphere*, pp. 421–434. Washington, DC: American Geophysical Union. See text for discussion of specific features shown. Snake River Plain profile from Schutt and Humphreys (2004); Deep Probe line from Yuan and Dueker (2005b); CD-ROM from Dueker et al. (2001); La Ristra line from Gao et al. (2004). Note the sharp velocity gradients associated with the Cheyenne belt, Farwell Mountain, Colorado Mineral Belt, and Jimez sutures and the apparent continuity of those sutures across multiple vertical seismic profiles.

a plume. Superficially, the evidence for a plume is convincing, and recent tomograms seem to reveal an NW-dipping plume-like structure in the upper mantle extending to a depth of perhaps 600 km (**Figure 6**; Yuan and Dueker, 2005a). The velocity anomalies shown in these P-wave images are particularly strong in the upper 150 km, where they reach values of 8% peak to peak. Similar very low velocities are seen in the upper mantle to depths of at least 200 km along the axis of the SRP as it trends ENE toward Yellowstone (Schutt and Humphreys, 2004). Beneath Yellowstone itself, the low P-wave velocity anomaly extends to depths well into the transition zone, although anomalies decrease from about 3% at 150 km depth to values less than 1% at a depth of about 450 km (Dueker and Yuan, 2004; Yuan and Dueker, 2005a). The extension of the low-velocity anomaly coincides at the transition zone with a 12 km depression of the 410 km discontinuity (**Figure 6**). The tomographic images shown in Yuan and Dueker suggest that a high-velocity 'curtain' extends from beneath the Wind River Range in the Wyoming Craton to a depth of about 250 km along a mantle trajectory that is roughly parallel to that of the postulated plume. Yuan and Dueker speculate that this feature represents a downwelling of the lower lithosphere. In the overall context of strong velocity contrasts of at least 8% in V_p that are seen throughout the region of western North America, however, the images shown in **Figure 6** may not be conclusive evidence for either a plume or a downwelling.

1.16.3.1.2 Southern Rocky Mountain region

It is noteworthy that velocity anomalies imaged beneath the relatively young (12 Ma) volcanic fields at the southeastern end of the SRP/Deep Probe NW–SE transect (**Figure 5(a)**) exhibit peak-to-peak values (~8%) comparable to those seen beneath YS (Dueker and Yuan, 2004). Velocity anomalies in this range, if solely thermal, are indicative of variations on the order of 200–400 °C, yet these volcanic fields are

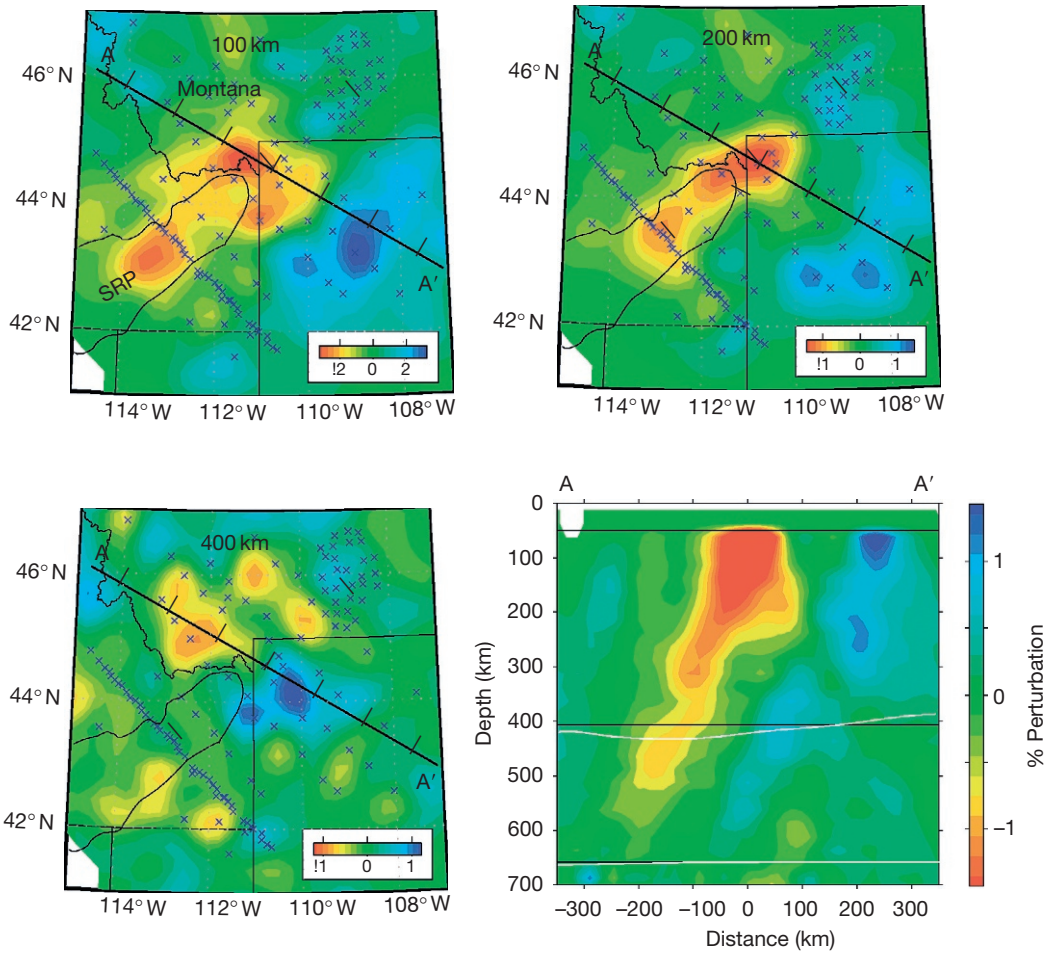

Figure 6 Tomographic images interpreted to show the presence of a NW-dipping plume beneath the Yellowstone 'hot spot.' The first five panels are depth slices approximately centered on Yellowstone (low-velocity perturbation near the intersection of cross-sectional lines). SRP denotes Snake River Plain along which the hotspot trace has migrated NE during the past 12 My. Lower right-hand panel is a vertical cross section along line A–A′. The velocity anomaly interpreted as a plume is shown as a NW-dipping feature penetrating into the transition zone and depressing the 410 km discontinuity (white line, 2× vertical exaggeration). The 660 km discontinuity is not uplifted in these images, as might be expected if the Yellowstone hotspot source were a deep-mantle plume. Adapted from Yuan H and Dueker KG (2005) Teleseismic P-wave tomogram of the Yellowstone plume. *Geophysical Research Letters* 32(L07304): 1–4. http://dx.doi.org/10.1029/2004GL022056.

volumetrically minor compared with that of YS/SRP. This repeated cycle of strong localized low-velocity anomalies along NE–SW striking zones continues into the southern Rocky Mountains, across the Saint George lineament, the Colorado Mineral Belt (the Aspen anomaly), and across the Jemez Lineament to the south (Figure 5). These 'fingering' zones of sharp velocity contrast, or sutures, are interpreted by Karlstrom et al. (2005) to be the result of varying response of Proterozoic lithosphere to mantle heating from below. While the source of sublithospheric heating and the varying lithospheric response to it remain controversial, it may be associated at least in part with lithospheric hydration during flat subduction in the Laramide and subsequent influx of hot asthenospheric material as the slab rotated downward and sank into the deeper mantle (e.g., Humphreys et al., 2003).

The Cheyenne belt is a major tectonic boundary, widely interpreted to be a crustal manifestation of a suture between the Archean Wyoming Craton to the north and a Proterozoic island arc terrane to the south (Figure 5). A comprehensive synthesis is given in Karlstrom et al. (2005). A north-dipping high-velocity anomaly in the upper mantle has been interpreted by some to mark the remnants of a failed subducting slab (Figure 5). The crust beneath the southern Rocky Mountain region attains its greatest thickness of about 50–60 km beneath the Cheyenne suture (Snelson et al., 2005), consistent with crustal foreshortening during subduction zone convergence.

1.16.3.1.3 Rio Grande Rift and Colorado Plateau

The LA RISTRA broadband seismic experiment composed 54 stations deployed along a NW–SE transect to explore the complex region south of the Rocky Mountains that extends from the western Great Plains of stable North America, across the Rio Grande Rift and the Jemez Lineament, and into the central region of the Colorado Plateau. A map of station deployment and a schematic of the crust and mantle along the transect are shown in Figure 7(a) and 7(b). LA RISTRA data were analyzed to obtain body wave and surface wave tomographic images, as well as receiver function images of the crust and upper mantle across the region (Gao et al., 2004; West et al., 2004a,b; Wilson et al., 2005a,b). The crustal and upper-mantle structures beneath the Rio Grande Rift stand out as a particularly prominent feature. Wilson et al. (2005a) showed that the Moho beneath both the Great Plains and the Colorado Plateau is at about 40–50 km depth, whereas the crust beneath the central region of the Rio Grande Rift thins symmetrically to about 35 km (Figure 7(c)). The thinned crust overlies a zone of very low velocities seen in superimposed tomographic images (Gao et al., 2004; West et al., 2004b) shown in (Figure 7(c)), confirmed by interstation Pn velocities of 7.8 km s^{-1} measured along the rift axis (Lastowka and Sheehan, 2005). The composite structures shown in Figure 7(c) exhibit symmetry around the axis of the Rio Grande Rift that has been interpreted to imply pure shear extension (Wilson et al., 2005b). No deep-mantle source has yet been observed seismically beneath the rift. The discontinuity at a depth of ~250 km in Figure 7(c) is suggested by Wilson et al. (2005a) to be the base of a continental asthenospheric low-velocity channel but this remains a speculation. Both the 410 and 660 km discontinuities are observed to be flat beneath the Rio Grande Rift, suggesting that whatever thermal anomaly caused the Rio Grande Rift, it does not extend to the upper-mantle transition zone.

The Colorado Plateau, adjoining the Rio Grande Rift to the NW along LA RISTRA line, is seen both geologically and in seismic images to be a stable block with a relatively high-velocity lithospheric lid that extends to a depth of at least 120 km (West et al., 2004b). West et al. found no suggestion of a sharp lithosphere/asthenosphere boundary beneath the Colorado Plateau, where the lithosphere appears to transition gradually to the asthenosphere between about 120 and 150 km depth (although see Lastowka and Sheehan, 2001, for a much thinner lithosphere). In contrast to the mantle structure beneath the western Great Plains, a low-velocity channel extends nearly to 300 km beneath the lithosphere of the Colorado Plateau (West et al., 2004b). This significant low-velocity channel may account for part of the higher elevations of the Colorado Plateau compared to the Great Plains, despite comparable crustal thickness (West et al., 2004b). The crust beneath the Colorado Plateau is estimated from receiver functions to be about 45–50 km thick (Gilbert and Sheehan, 2004; Wilson et al., 2005a). That crustal thickness varies, however, with thinning to the north (Gilbert and Sheehan, 2004) accompanied by no corresponding change in elevation (Figure 8). Whereas Wilson et al. suggested that much of the Colorado Plateau uplift is due to a low-velocity channel in the upper mantle, Gilbert and Sheehan suggested that most of the Colorado Plateau uplift is due simply to isostatic compensation of the crust, although they acknowledged that hot, low-density mantle may contribute to plateau support (Gilbert and Sheehan, 2004).

1.16.3.1.4 Great Basin

The western edge of the Colorado Plateau where it abuts the eastern Great Basin marks a profound lithosphere boundary. This is seen in both crustal thickness (Figure 8) and upper-mantle velocity (Gilbert and Sheehan, 2004; Lastowka and Sheehan, 2001). The Great Basin, which locally has undergone up to 100–200% extension, is characterized by thin (35 km) crust, low upper-mantle velocities, and high heat flow. Large-scale, highly detailed, crustal studies based on controlled-source experiments have been extensively reviewed previously (Smith et al., 1989), but portable array broadband experiments carried out since, including those discussed earlier in the text and in the Colorado Plateau–Great Basin PASSCAL experiment, have substantially increased the 3-D image of crustal thickness (Gilbert and Sheehan, 2004). Crustal thickness as determined from receiver functions varies within the Basin and Range Province from slightly more than 35 km to less than 30 km in northern Utah and Nevada and southeastern Oregon (Figure 8). The broadband experiments have also contributed substantial new information on uppermost-mantle velocities, which were generally known from previous refraction and surface wave studies to be low, with V_s about 4.2–4.3 km s^{-1} and $V_p \sim 7.8$ km s^{-1}. Recent surface wave and Pn studies have confirmed the absence of a high-velocity lid in the uppermost mantle beneath the crust of the Great Basin (Lastowka and Sheehan, 2001), and this appears to be the case throughout both the southern and northern Great Basin.

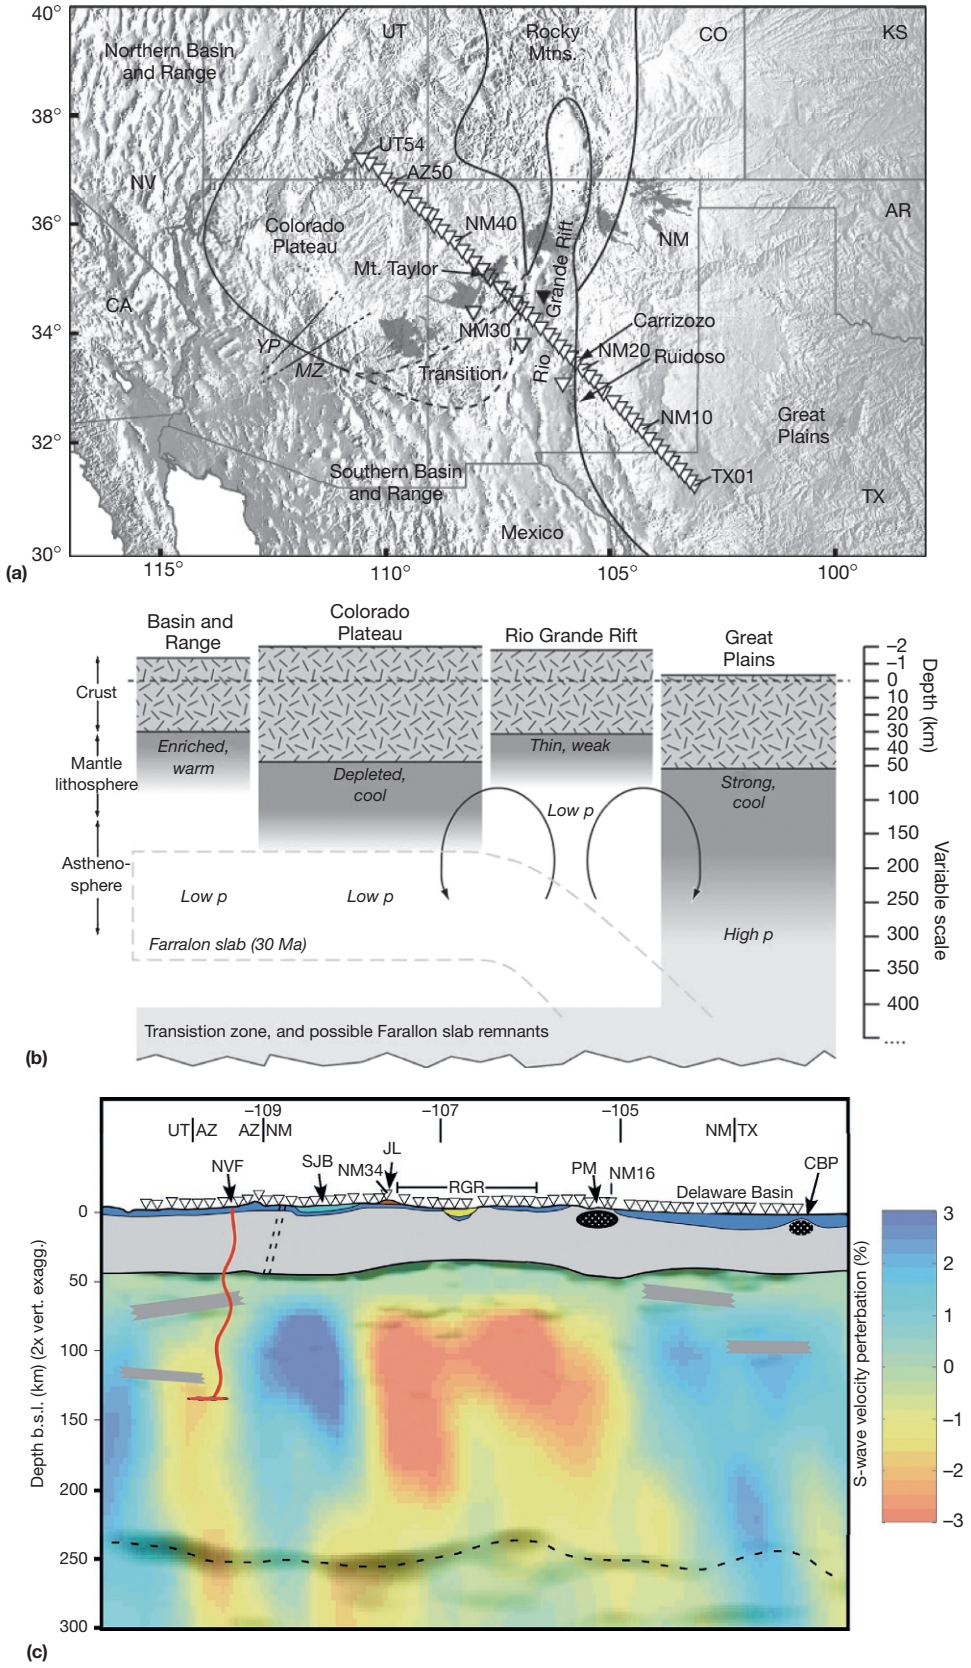

Figure 7 (a) Map showing the 57 seismic stations of the La Ristra broadband transect that extends from the Great Plains into the Colorado Plateau. (b) Schematic cross section showing hypothetical variations between major geologic blocks from the Great Plains of stable North America into the

(Continued)

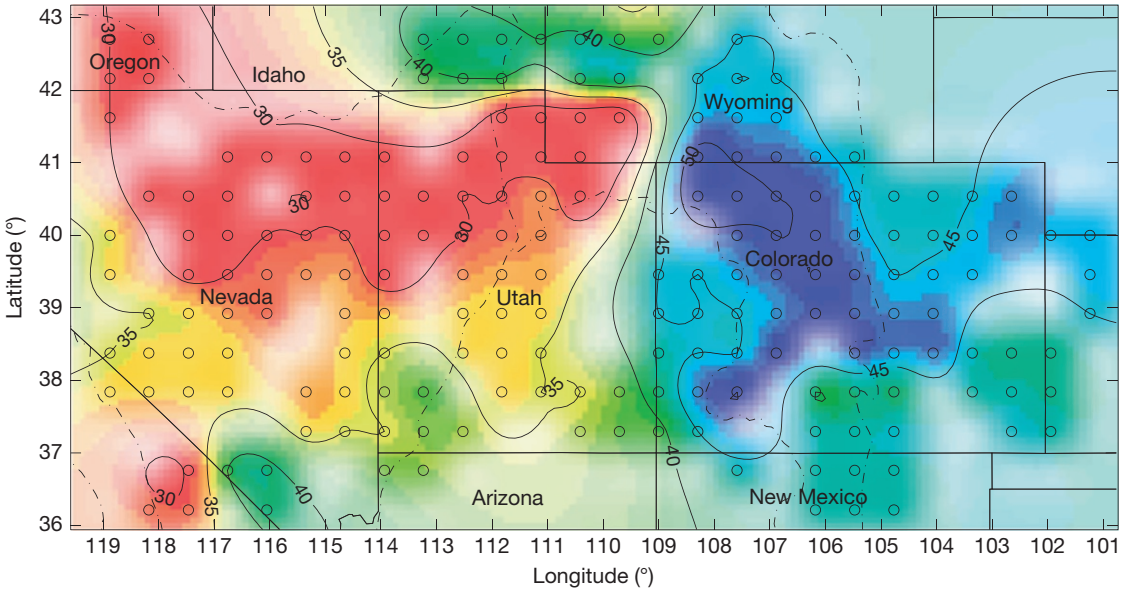

Figure 8 Contour map of crustal thickness in central western United States, primarily based on receiver functions. Red indicates thinner crust; blue, thicker crust. Circles denote crustal thickness binning points from which contours were drawn. Dashed lines mark boundaries between (from west to east) the Great Plains, Rocky Mountains, Colorado Plateau, and Basin and Range Province. Modified from Gilbert HJ and Sheehan AF (2004) Images of crustal variations in the intermountain west. *Journal of Geophysical Research* 109: B03306.

1.16.3.1.5 Sierra Nevada

The Great Basin extends westward to the Sierra Nevada range where seismic and geologic evidence for crustal extension ceases. Receiver function analyses from portable array experiments in the southern Sierra Nevada Mountains of California suggest the possibility that part of the crustal root of the Sierra Nevada volcanic arc has foundered following the cessation of arc activity in the Sierras about 16 Ma (Zandt et al., 2004). The foundering model is based on an unusual absence of a Moho signature in the receiver functions for conversion points beneath the Great Valley. There, the asthenospheric backflow following the cessation of Farallon Plate subduction is posited to have removed a root of dense ultramafic residue formed during the building of the great Sierra Nevada Batholith. Such destabilization and sinking are commonly cited in the literature, but are always inferred from indirect observations as in the Zandt et al. study. Current broadband experiments in the planning stages or now being implemented for California, Chile, and the North China Craton are aimed at the direct imaging of such possible lithospheric delamination, the models for which remain quite hypothetical.

1.16.3.2 Indian–Eurasian Continental Collisional Zone

1.16.3.2.1 Crustal structure

The Tibetan Plateau and adjacent regions that include Nepal, Tien Shan, Hindu Kush, and Karakoram have been among the most intensively studied structures in the world. Over the past decade and a half, hundreds of portable broadband seismometers have been deployed as part of major international experiments (e.g., Kind et al., 2002; Klemperer, 2006; Kosarev et al., 1999; Kumar et al., 2005; Schulte-Pelkum et al., 2005; Wittlinger et al., 2004; Zhao et al., 2001; **Figures 1** and **9**). Logistical constraints have tended to limit the Tibetan Plateau deployments to transects along roads (**Figure 9(a)**), whereas the Nepal, Tien Shen, and Karakoram deployments were aerially distributed in 2-D arrays (**Figure 9(b)** and **9(c)**; see Klemperer (2006) for a comprehensive summary (with map) of passive and active seismic experiments).

Receiver function imaging of both crustal thickness and lithospheric plate deformation in the Indian–Eurasian continental collision zone has been a prominent objective of most Himalayan and Tibetan Plateau broadband experiments.

Figure 7 (Continued) actively extending Basin and Range Province. Approximate location of the Farallon slab c.30 Ma is shown for reference. (a) and (b) adapted from West M, Ni, JF, Baldridge WS, et al. (2004) Crust and upper mantle shear-wave structure of the Southwest United States: Implications for rifting and support for high elevation. *Journal of Geophysical Research* 109(B03309): 1–16. http://dx.doi.org/10.1029/2003/JB002575. (c) Crustal and upper-mantle schematic of the region across the Rio Grande Rift (RGR) in relation to other surface geologic features along the La Ristra transect including the Navajo volcanic field (NVF), San Juan Basin (SJB), Jemez Lineament (JL), Pajarito Mountains (PM), and Central Basin Platform (CBP). Reproduced from Wilson D, Aster R, Ni JF, et al. (2005) Imaging the seismic structure of the crust and upper mantle beneath the Great Plains, Rio Grande Rift, and Colorado Plateau using receiver functions. *Journal of Geophysical Research* 110(B05306): 1–14. http://dx.doi.org/10.1029/2004JB003492. Crustal thickness from receiver functions and other receiver function discontinuities (gray areas) are superimposed on the body wave tomographic image of the upper mantle from Gao et al. (2004). The apparent discontinuity around 250 km depth (dashed line), based on receiver functions, is speculated by Wilson et al. to be the Lehmann discontinuity, perhaps indicating the base of the continental asthenosphere (Wilson et al., 2005a). It is not explained in this interpretation, however, why the depth of the discontinuity is so little affected by the major Rio Grande Rift velocity (thermal) anomaly. The signal appears to vanish beneath the stable central basin.

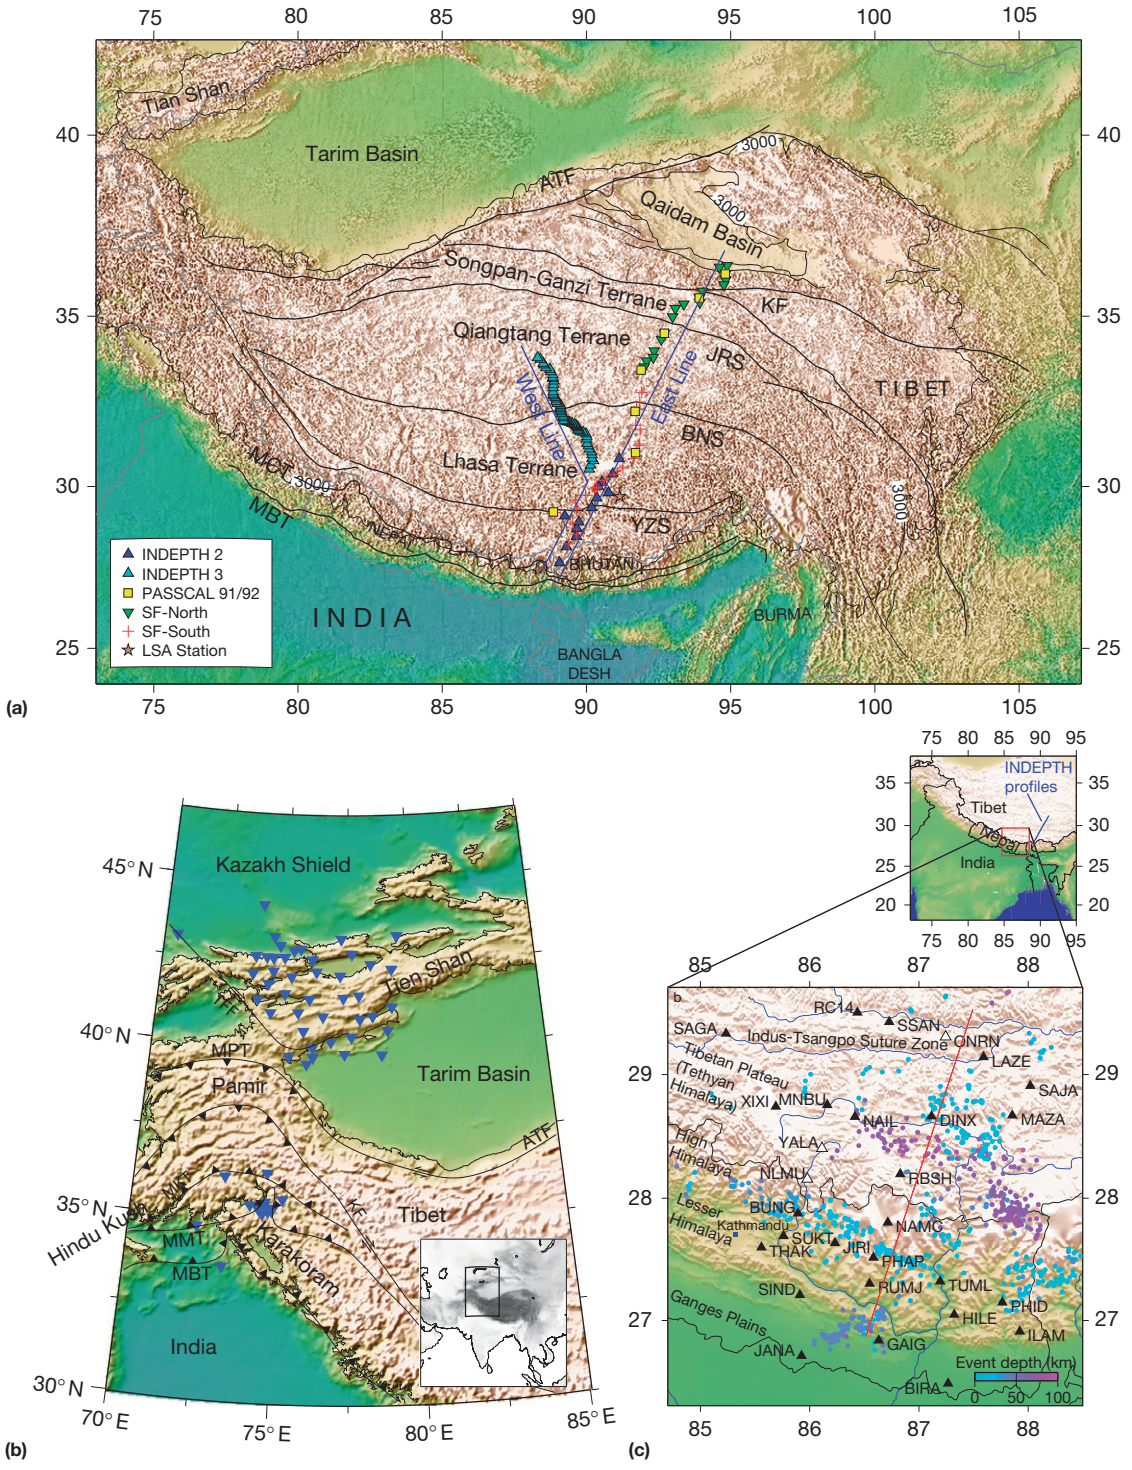

Figure 9 (a) Summary of broadband seismic experiments in central Tibet c.2002 superimposed on topographic map of Tibet showing major terrane boundaries. Reproduced from Kind R, Yuan H, Saul J, et al. (2002) Seismic images of crust and upper mantle beneath Tibet: Evidence for Eurasian plate subduction *Science* 298: 1219–1221. The experiments include PASSCAL experiments PASSCAL 91/92 and INDEPTH 2 and 3, as well as Sino-French experiments as shown. Abbreviations from Kind et al. (2002) are as follows: MBT, Main Boundary Thrust; MCT, Main Central Thrust; YZS, Yarlung–Zangbo suture; BNS, Bangong–Nujiang suture; JRS, Jinsha River suture; KF, Kunlun fault; ATF, Altyn–Tagh fault. An up-to-date summary of seismic experiments, both passive and active, in that region of Tibet can be found in Klemperer (2006). (b) Summary of portable and permanent broadband seismic stations deployed in western Tibet superimposed on a topographic map with major tectonic terranes indicated. Reproduced from Kumar P, Yuan X, Kind R, Kosarev G (2005) The lithosphere–asthenosphere boundary in the Tien Shan-Karakoram region from S receiver functions: Evidence for continental subduction. *Geophysical Research Letters* 32(L07305): 1–4. http://dx.doi.org/10.1029/2004GL022291. The largest array was composed of 28 portable stations in central and western Tien Shan (the GHENGIS experiment). The small six-station array of the NANGA experiment was clustered in Nanga Parbat near the inflection in the Main Mantle Thrust (MMT). The portable stations complemented a number of permanent stations, including most notably the permanent KNET array in Kyrgyz. Abbreviations from Kumar et al. (2005) are as follows: MPT, Main Pamir Thrust; MKT, Main Karakoram Thrust; MMT, Main Mantle Thrust; MBT, Main Boundary Thrust; TFF, Talasso–Ferghana fault; KF, Karakoram fault; ATF, Altyn–Tagh fault. (c) Topographic map showing locations of 29 portable broadband stations (black triangles) deployed to study the structure of the Indian Plate where it plunges beneath the Himalayas and Tibet. Reprinted from Schulte-Pelkum V, Monsalue G, Sheehan A, et al. (2005) Imaging the Indian subcontinent beneath the Himalaya. *Nature* 435: 1222–1225, Copyright (2005), with permission from Macmillan Publishers Ltd. The position of the array relative to INDEPTH profiles is shown in the upper location map. Hypocentral depths for events located by the array are shown as small color-coded filled circles. The red line indicates the surface trace of the vertical cross section shown in **Figure 10**.

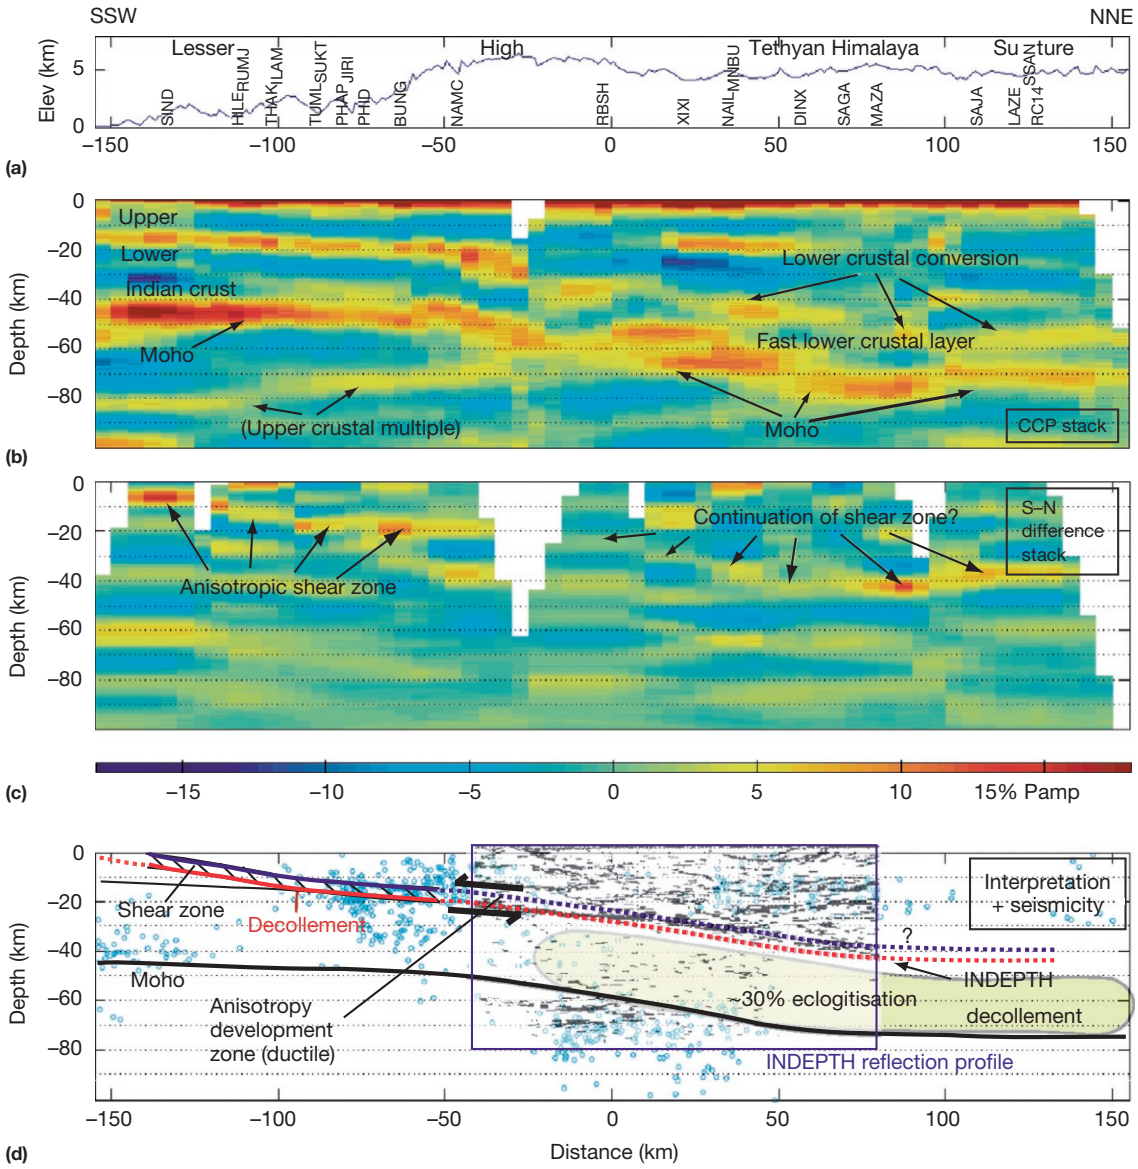

Figure 10 Migrated receiver function common conversion point (CCP) stack image along the NNE–SSW transect that is shown as a red line in **Figure 9(c)**. (a) Topography cross section along profile. (b) CCP receiver function stack, where red indicates positive conversion amplitude (velocity increase) and blue, negative amplitude (velocity decrease). Color intensity is proportional to receiver function amplitude. (c) Differenced S–N CCP stack, with amplitudes of receiver functions from southern azimuths differenced with those from northern azimuths to image arrivals that change polarity by back-azimuth (see Schulte-Pelkum et al., 2005, for further explanation). (d) Interpretive cross section based on (b) and (c). INDEPTH reflection profile and local seismicity are superimposed (see text for further discussion). Reprinted from Schulte-Pelkum V, Monsalue G, Sheehan A, et al. (2005) Imaging the Indian subcontinent beneath the Himalaya. *Nature* 435: 1222–1225, Copyright (2005), with permission from Macmillan Publishers Ltd.

Schulte-Pelkum et al. (2005) had used receiver functions to map the Indian lithosphere as it plunges beneath the Himalayas and Tibet (**Figure 10**), revealing the apparent presence of a strong décollement where the uppermost part of the Indian Plate is thrust beneath the Himalayas. The Moho is similarly thrust to great depth. Schulte-Pelkum et al. speculated that the lower crust is partially converted to eclogite in the process, as shown schematically in the lower panel of **Figure 10**. In the central Tibetan Plateau itself, data from the INDEPTH experiments and early PASSCAL experiments have been extensively analyzed to produce images of Moho and upper-mantle structures, not all of which are entirely consistent between studies even with the same dataset. Remarkably, the Moho thickness beneath the entire region of these experiments (**Figure 9**) varies only from a maximum of about 78 km to a minimum of 65 km, with no systematic change inferred either across the Tibetan Plateau or at major fault boundaries (Kind et al., 2002; Kosarev et al., 1999). Results from these same data seem to indicate that V_p/V_s also does not vary significantly between northern and southern Tibet (Kind et al., 2002). This lack of significant variation in either crustal thickness or crustal velocity led Galve et al. (2002) to examine the Moho

structure in detail for clues as to the mechanism for crustal thickening. Results from their combined receiver function/wide-angle reflection study aimed specifically at detailed Moho structure suggest that the Moho has a complex architecture with "dipping and overlapping segments indicating lithospheric imbrication" (Galve et al., 2002, p. 1). Wittlinger et al. (2004), using S-to-P-converted wave receiver functions, reported a similarly complex and warped Moho structure.

Rapine et al. (2003) measured fundamental-mode Rayleigh wave dispersion to study contrasts in crustal structure beneath northern and southern Tibet. They concluded that a low-velocity layer in the middle crust is required by the dispersion data in southern but not northern Tibet. This is also suggested by Wittlinger et al. (2004) from Sp receiver functions. Moreover, there is general agreement that the lower crust beneath southern Tibet has higher velocity than that of the north and that it is underlain by the mantle with a positive velocity gradient. Rapine et al. interpreted these findings as the result of underthrusting of the Indian continental lithosphere, where the low velocities in the middle crust reflect H_2O-induced melting in the interplate shear zone between underthrust Indian crust and overriding Asian crust. No similar middle crustal low-velocity zone is found in the crust of northern Tibet, although the S-wave velocities in both the crust and mantle of northern Tibet are significantly lower than those in the south. This result is consistent with many other studies, including that of Kind et al. (2002), suggesting that mantle temperatures in northern Tibet are higher by several hundred degrees than those in southern Tibet. The source of that difference – mantle diapir or lithospheric delamination, for example – remains a debated issue.

1.16.3.2.2 Seismic structure of the uppermost mantle

Early studies by Kosarev et al. (1999) of the mantle beneath the eastern Tibetan Plateau appeared to show a northward-dipping discontinuity in the 100–300 km depth range colliding with a southward-dipping Asian lithosphere. They identified the northward-dipping feature as the cold and depleted lithosphere of India plunging beneath the Asian lithosphere. A continent-scale study by Friederich (2003) using S waves and surface waves similarly finds a northward-dipping slablike feature beneath southern Tibet that he interpreted to be the underthrust Indian lithosphere. Detailed imaging by Kind et al. (2002), however, fails to reveal a northward-dipping discontinuity, but it does confirm the existence of a southward-dipping feature interpreted as detached Asian lithospheric mantle (ALM; **Figure 11**). Kind et al. suggested that the Indian continent has been underthrust subhorizontally beneath Tibet and that it has a broken, nearly vertical northern edge.

There is surprisingly little indication that the massive effects of continental collision have significantly perturbed the 410 and 660 km discontinuities in the upper-mantle transition beneath Tibet. Kind et al. (2002) reported that in both the eastern and western sections across Tibet (**Figure 9**), the vertical separation between the 410 and 660 km discontinuities is virtually constant along the two studied transects (**Figure 11**), implying a N–S variation in transition zone temperature less than 50°. They inferred from these results that there is no lithospheric slab penetration into the transition zone, suggesting that the leading downgoing oceanic plate may already have detached from the Indian continent. Both the 410 and 660 km discontinuities appear to bend downward beneath the northern Plateau, a probable artifact of a south to north decrease in S-wave velocity of about 5% in the upper mantle, consistent with a northward increase in the average temperature of perhaps 300 °C.

Extensive portable array deployments have complemented a growing population of permanent broadband stations in the Tien Shan and Karakoram regions at the western edge of the Indo-Asian collision belt (**Figure 9**). Kumar et al. (2005) employed the S-to-P receiver function method to image both crustal thickness and the lithosphere–asthenosphere boundary (LAB) in the region (**Figure 12**). If their interpretation is correct, the results obtained for the LAB are among the very rare instances where that boundary has been successfully imaged. Moho depths, which vary from about 45–65 km beneath Tien Shan and increase to about 70 km beneath Karakoram, are apparently uncorrelated with what is seen as very significant differences in the LAB. As seen in **Figure 12** (top panel), the LAB from receiver functions is reasonably well correlated with the surface wave tomographic images of Friederich (2003). Along the north–south profile (top panel, approximately 75° E longitude in **Figure 9(b)**), the LAB deepens from less than 100 km beneath Tien Shan in the north to 270 km and more beneath Pamir and Karakoram in the south (Kumar et al., 2005). Kumar et al. interpreted the south-dipping LAB as the base of the subducting Asian plate where it is thrust beneath the high-velocity Indian mantle lithosphere. The east–west profile, roughly along 43°N latitude (**Figure 9(b)**), shows a relatively thin lithosphere even beneath the Kazakh shield (~130 km) and even thinner beneath Tien Shan itself (90–100 km), thickening again to almost 180 km beneath the Tarim Basin block, which appears to be subducting southward beneath northwestern Tibet (Wittlinger et al., 2004). Kumar et al. (2005) and others speculated that the Indian lithosphere is colder and stronger than is its Asian counterpart, as evidenced by the much thicker and higher-velocity lithosphere beneath the Indian continent.

A number of ongoing portable broadband experiments are underway on the eastern Tibetan Plateau and its flanking terranes, one focus of which is on measuring anisotropy to resolve the controversial issue of lower-crustal deformation as a mechanism of growth and collapse of the plateau. Notable among the eastern Tibetan deployments is the MIT China Seismic Array where 25 broadband stations have been recently installed (yellow squares in **Figure 1**). In addition, regions both north and south of the MIT array have seen dozens of stations deployed in recent years, although little has been published to date.

1.16.3.3 Continental Margin Subduction Zones

Continental margin subduction zones are among the more natural targets for broadband portable array seismology. The structures of particular interest are in the subduction zone itself, at mantle depths that are accessible primarily through passive array seismology. The continental regions most studied through the deployment of temporary portable arrays include the Andes, particularly the central Andes, the Cascade and Alaskan arcs, and the Mediterranean region (**Figure 1**).

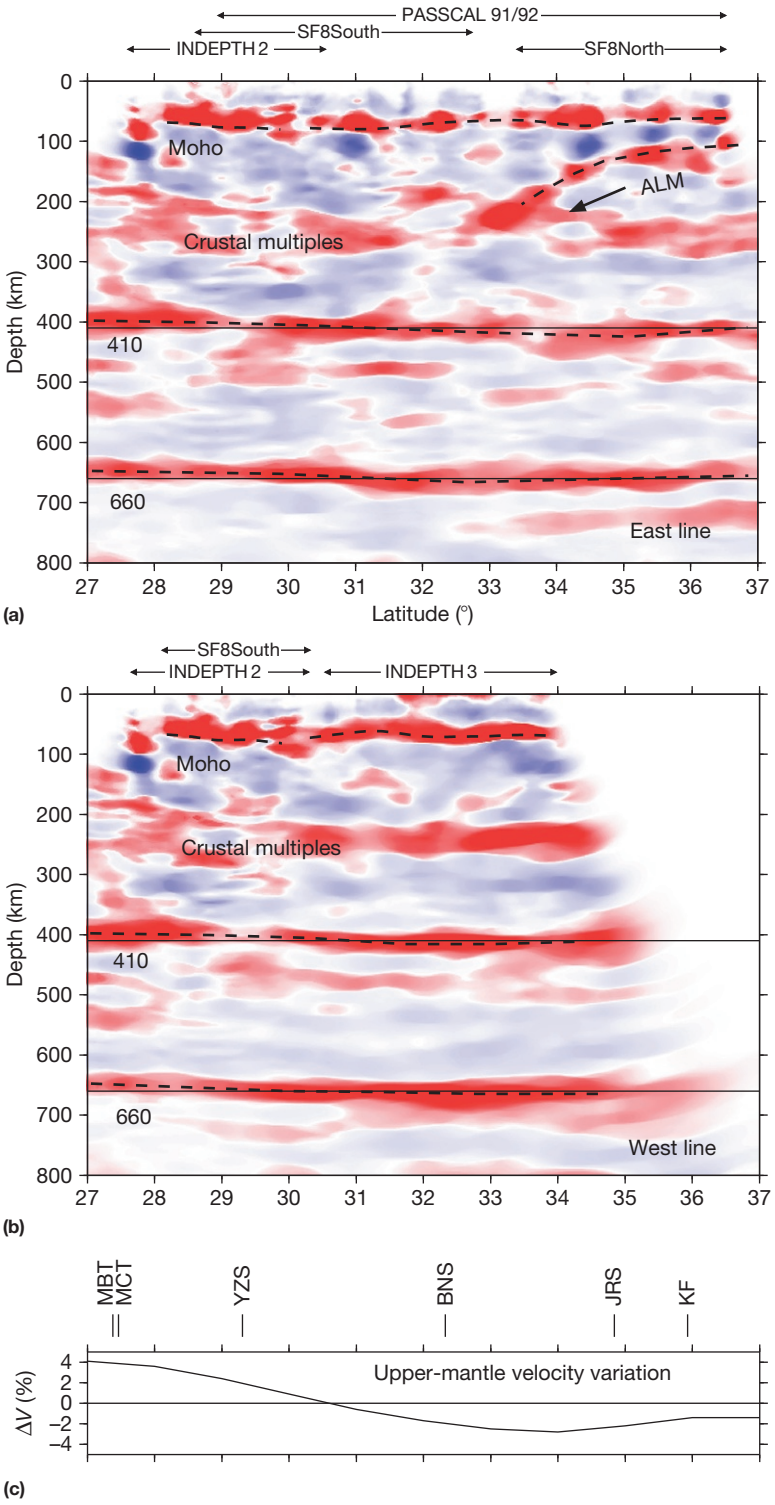

Figure 11 Migrated receiver function images along profiles shown in **Figure 9(a)**. (a) The approximately N–S profile (as in **Figure 9(a)**), based on PASSCAL 91/92, INDEPTH 2, and SF-South and SF-North passive array deployments. Positive amplitudes (velocity increase) are plotted in red; negative amplitudes in blue. ALM denotes underthrust Asian lithospheric mantle. 'Crustal multiples' around 200–300 km depth are produced by crustal reverberations. (b) Images from the NW–SE INDEPTH 3 transect, as well as the southern part of the (a) transect. Acronyms are as in caption to **Figure 9**. Reproduced from Kind R, Yuan H, Saul J, et al. (2002) Seismic images of crust and upper mantle beneath Tibet: Evidence for Eurasian plate subduction. *Science* 298: 1219–1221.

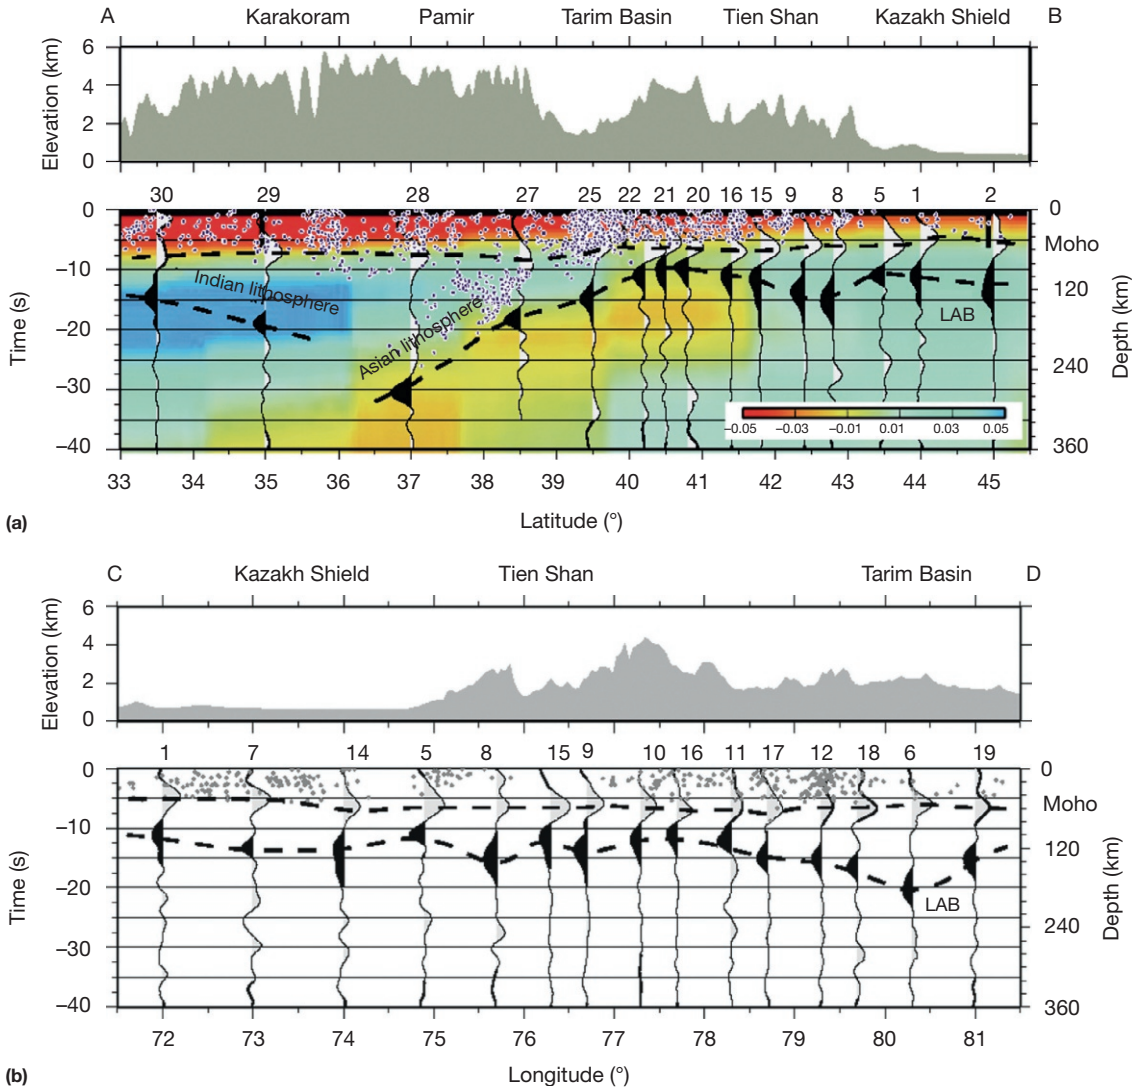

Figure 12 (a) North–south receiver function profile approximately along 75° E longitude in **Figure 9(b)**, overlaid on tomographic image of Friederich (2003). Topography is shown in the upper panel. Reproduced from Kumar P, Yuan X, Kind R, Kosarev G (2005) The lithosphere–asthenosphere boundary in the Tien Shan-Karakoram region from S receiver functions: Evidence for continental subduction. *Geophysical Research Letters* 32(L07305): 1–4. http://dx.doi.org/10.1029/2004GL022291. The receiver function signals in black are interpreted to correspond to the lithosphere–asthenosphere boundary (LAB) and suggest that the rigid Tarim Basin block of the continental Asian lithosphere is being underthrust beneath the Pamir and Karakoram Ranges while at the same time, the high-velocity Indian lithosphere appears to be dipping to the north. (b) East–west receiver function profile across Tien Shan, approximately along 43° N latitude in **Figure 9(b)**.

For a more comprehensive summary of subduction zone seismic studies, including those in Japan where data from extensive permanent networks have produced highly detailed images of subduction zone structures.

1.16.3.3.1 Andean studies

International broadband portable array deployments, largely by US and German groups, have been heavily concentrated in the central and southern Andes as shown in **Figure 13**. Migrated receiver function images beneath dense aerial deployments in northern Chile and Argentina reveal décollement thrusts within the crust, Moho depths up to nearly 80 km beneath the western Cordillera/western Altiplano but decreasing eastward into the Altiplano (Puna) and eastern Cordillera (**Figure 14**). The top of the descending Nazca Plate is clearly imaged to a depth of slightly more than 100 km, below which the discontinuity signal vanishes. Yuan et al. (2000) interpreted the disappearance of the upper plate boundary to be the result of the low-velocity oceanic basaltic crust converting to high-velocity eclogite.

Despite the large numbers of mostly short-period instruments deployed (e.g., PISCO, CINCA, ANCORP, and PUNA; **Figure 14**), the central Andes of northern Chile/Argentina has, with few exceptions (e.g., Graeber and Asch, 1999), seen relatively little in the way of comprehensive 3-D tomographic imaging. Farther south, however, in the vicinity of the broadband CHARGE experiment (**Figure 15**) where the slab transitions southward from flat to normal subduction, extensive

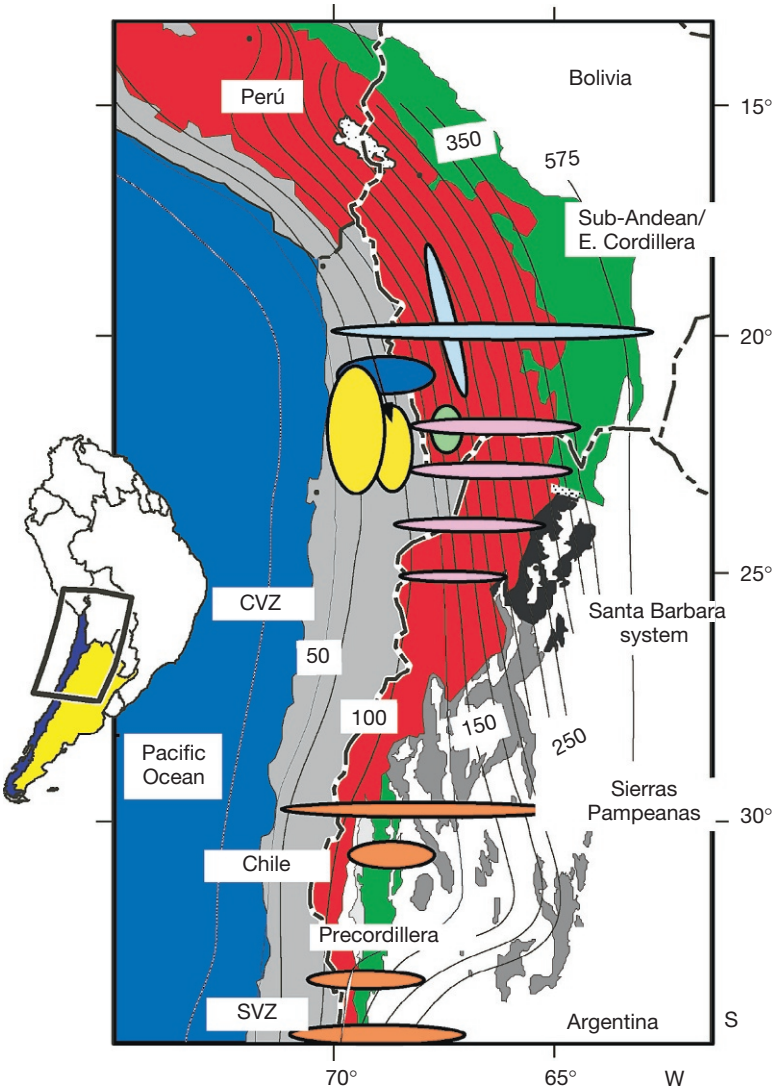

Figure 13 Map of the central and southern Andes showing approximate locations (colored ovals) of major seismic experiments during the past decade and a half. Figure courtesy of Sue Kay. Contoured depths are to Wadati–Benioff zone. CVZ, Central Volcanic Zone; SVZ, Southern Volcanic Zone. Explanation of ellipses and ovals: light blue, BANJO and SEDA deployments (e.g., Zandt et al., 1996); yellow, CINCA and PISO deployments (e.g., Schmitz et al., 1997); dark blue, ANCORP (ANCORP WorkingGroup, 2003). Brown ellipse, APMB experiment (e.g., Chmielowski et al., 1999). Pink, GFZ experiment (Yuan et al., 2000); see also **Figure 14**. Orange ellipses, CHARGE (Wagner et al., 2005); see also **Figure 15**.

tomographic imaging of both P and S waves has revealed a remarkable result (Wagner et al., 2005). Wagner et al. focused on the mantle lithosphere within the region of flat subduction around latitude 31°S and then southward into the region of normal subduction. As shown in **Figure 15**, V_p is as low as 7.4 km s^{-1} in the continental lithospheric mantle above the region immediately above the flat slab. Velocity values this low are not surprising in a region where it has been widely assumed that the overlying continental lithosphere is extensively hydrated by water sweated from the descending plate. Tomographic inversion for V_s, however, produces an entirely different result, with S-wave velocities relatively high ($\sim$4.6 km s^{-1}) in the same region of the continental lithosphere where very low P-wave velocities are observed (**Figure 15**). The result is an anomalously low Poisson's ratio (<0.25) that matches no plausible hydrated mantle mineralogy or even any common mantle mineralogy at all. Preliminary studies in Alaska have produced a similar result in the mantle above the descending slab, where V_p/V_s ratios of 1.62–1.68 are found in the overlying mantle wedge at depths greater than 80 km. Abers et al. (2005) speculated that the low V_p/V_s may indicate large-scale silica addition to the overlying mantle wedge, presumably the result of tectonic erosion of the overriding continent, but the issue remains essentially unresolved as of this writing. Further data on the structure of the continental lithosphere above regions of flat subduction are being collected in the region of northern Chile where subduction transitions from normal to flat (white square in **Figure 13**). Here, a large-scale regional array of 25 broadband and 45 short-period instruments is currently being deployed to image possible continental lithosphere delamination. This region of Chile and Argentina is one of the few places in the world where lithospheric delamination

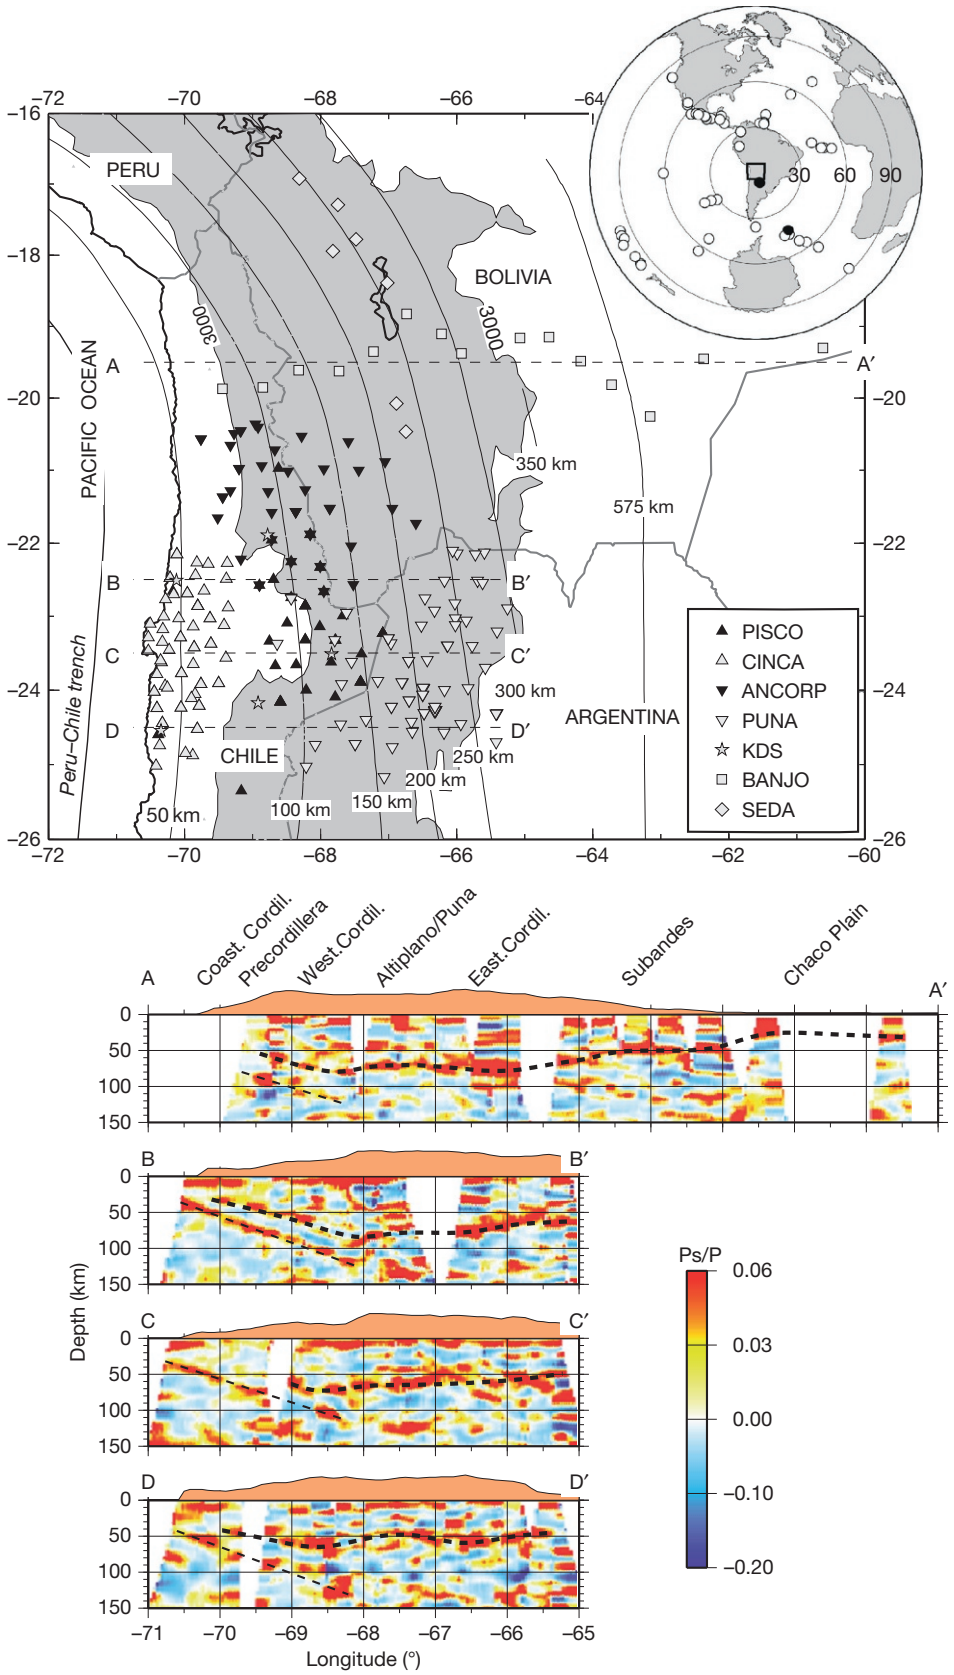

Figure 14 Migrated receiver function images (lower images) based on the combined data of several short-period and broadband experiments (map in the upper panel) across the south-central Andes. Map figure shows locations of passive seismic stations as indicated in relation to cross-sectional lines of receiver function images in the lower panels. Contours show depth to top of Wadati–Benioff zone. Small black triangles indicate volcanic centers. Shaded region above 3 km elevation. Lower panels represent a series of vertical cross sections along the E–W profiles indicated in the map figure. The heavy black dashed line marks the Andean Moho, the lightly dashed lines the top of the descending Nazca Plate (Yuan et al., 2000). The crust tends to thin eastward of the volcanic arc (beneath the Altiplano and eastern Cordillera), without a corresponding decrease in average surface elevation. Reprinted from Yuan X, Sobolev SV, Kind R, et al. (2000) Subduction and collision processes in the Central Andes constrained by converted seismic phases. *Nature* 408: 958–961, Copyright (2000), with permission from Macmillan Publishers Ltd.

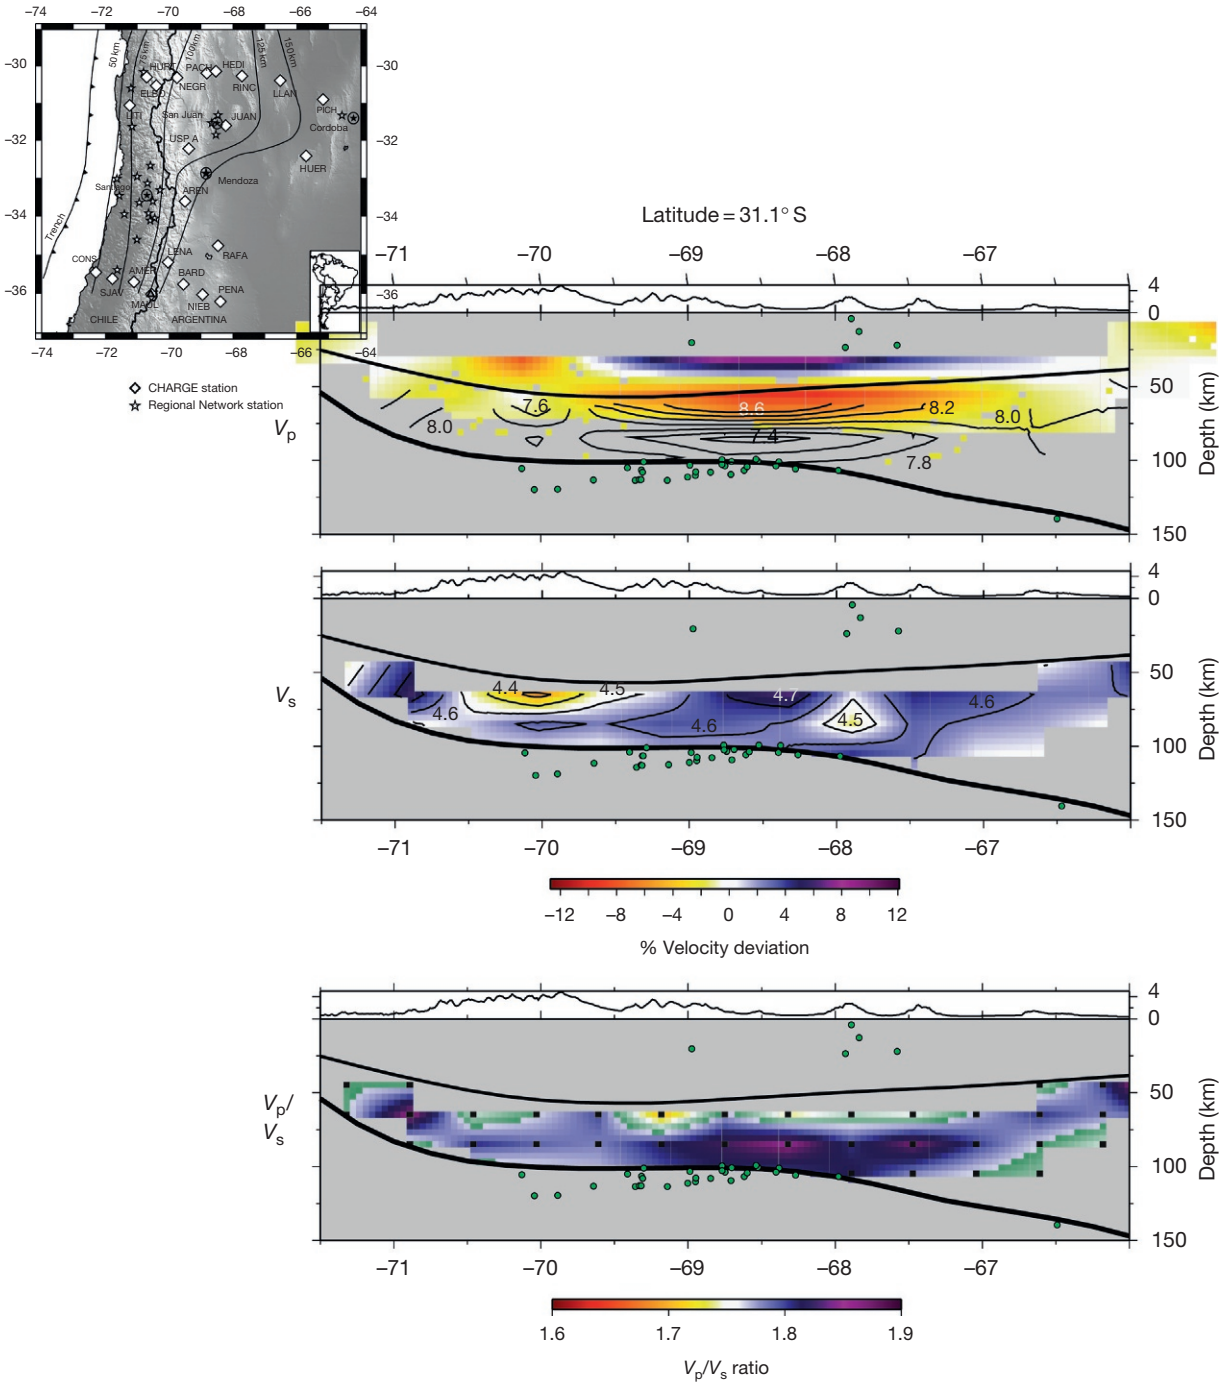

Figure 15 Broadband seismic experiment (CHARGE) across the southern Andes of central Chile in the region of flat subduction and the transition from flat to normal subduction. East–west tomographic images across the region of flat subduction near latitude 31° S reveal a prominent zone of low V_p/V_s ratio (deep blue in the lowermost panel) in the continental lithosphere immediately above the flat subducting plate, as yet unexplained by any plausible mantle mineralogy. Adapted from Wagner LS, Beck SL, and Zandt G (2005) Upper mantle structure in the south central Chilean subduction zone (30 to 36S). *Journal of Geophysical Research* 110. http://dx.doi.org/10.1029/2004JB0003238.

may be actively occurring today, speculated to be the result of slab rollback as the downgoing Nazca Plate transitions from flat subduction back to normal subduction (Kay et al., 1994).

The Andes are at their widest and highest in the central region of Peru and Bolivia where subduction is 'normal.' There, the primary questions concern the origin of the high Altiplano, which, next to the Tibetan Plateau, is the second largest high plateau in the world. Van der Lee et al. (2001a) used surface wave data of mostly South American events recorded on several portable arrays in Peru, Chile, Bolivia, and Brazil to determine structure above the subduction zone and across the central part of South America. One of the most

notable features shown by that study is a prominent low-velocity upper mantle beneath the eastern Andes (the foreshortened region of the high Andes, interpreted previously to be affected by mantle hydration from an episode of flat subduction in Miocene time; James and Sacks, 1999). The seismic images are consistent with predicted effects of lithospheric hydration (during flat subduction) followed by lithospheric melting resulting from the infusion of hot asthenospheric material into the opening mantle wedge during slab foldback to normal subduction.

1.16.3.3.2 Central America and Caribbean

The Caribbean and western Central America are targets for a number of ongoing passive array experiments and combined active and passive source experiments, from which results are as yet mostly unpublished. Notable among the larger projects are the BOLIVAR experiment in NE Venezuela and the TUCAN experiment in Costa Rica and Nicaragua (station locations shown in Figure 1). The BOLIVAR experiment, a combination of onshore and offshore active and passive source methods and instrumentation, is aimed at studying the accretion of arc-related terranes in northern Venezuela. This work is a substantial extension of a previous broadband array experiment in which it was found that continental South America has overridden a significant part of the Lesser Antilles arc, with the southern detached slab now situated beneath NE Venezuela (VanDecar et al., 2003).

1.16.3.3.3 Cascadia

The 1993 Cascadia experiment (CASC93) was, in 1993 and even today, an unprecedented effort at broadband deployment – in the number of instruments, the extraordinarily high station density, and the length and linearity of the transect (Nabelek et al., 1993). CASC93 was composed of 44 broadband stations located at 69 sites at approximately 5 km station spacing along an almost perfectly straight transect across the Cascades, from coastal to central Oregon (Figure 16). The dataset has proved a fertile testing ground for advanced multichannel imaging of scattered waves in a subduction zone (Rondenay et al., 2001). The results from that imaging and an interpretive overlay are shown in Figure 16 (lower panel). Bostock et al. (2002) had interpreted the images in Figure 16 to be the result of eclogitization of the downgoing slab (below about 45 km) and consequent serpentinization of the overlying mantle wedge in the forearc. It is anomalous that the basalt–eclogite transition in this case is far shallower than is generally presumed for typical subduction zones (45 km vs. 100 km), but the disappearance of a basaltic crustal signature below 45 km appears to have few other explanations. Similarly, the disappearance of a continental Moho signature in the images (around 122.5 longitude) appears to be the result of an 'inversion' in the usual continental Moho velocity transition. Thus, the (relatively) high-velocity material of the lower continental crust is interpreted to be in contact with (relatively) low-velocity serpentine of the heavily hydrated mantle wedge (serpentinized mantle forearc in the lower frame of Figure 16).

1.16.3.3.4 Alaska

The Broadband Experiment Across the Alaska Range (BEAAR) experiment (Figure 17) provides another example of imaging across a very complex continental subduction boundary (Abers et al., 2006). The BEAAR transect, 1999–2001, consisted of 39 broadband seismographs deployed with 10–15 km station spacing normal to the strike of the subduction zone (map, Figure 17). High-resolution receiver function images (Ferris et al., 2003) show that the top of the slab is low velocity (i.e., basaltic) to a depth of about 130 km (note the contrast with the Cascadia images in Figure 16). Moreover, the Wadati–Benioff zone of seismicity is angled slightly more steeply than the top of the imaged slab, suggesting that the earthquakes gradually migrate deeper into the slab with depth (Figure 17). Well-constrained seismic attenuation determinations (Stachnik et al., 2004) show high attenuation in the mantle wedge beneath the Alaska Range, but where the slab is less than about 75 km depth, there is an observed sizeable volume of very low-attenuation material (Figure 17). This zone of low attenuation has been interpreted by Abers et al. (2006) to indicate that a cold, hydrous viscous 'nose' has formed in the corner of the mantle wedge and remains isolated from the counterflow in the main part of the mantle wedge. The presence of a high-velocity viscous 'nose' in the subduction zones has been observed previously in Japan and given much the same explanation (Kincaid and Sacks, 1997; Sacks and Suyehiro, 2003).

1.16.3.3.5 Kamchatka

The subduction zone along the Kamchatka Peninsula exhibits a unique geometry in that it undergoes a nearly right-angle change in strike at the intersection of the eastern extension of the Aleutian Arc and the NE trending Kamchatka arc (Figure 18; Lees et al., 2000). This so-called Aleutian–Kamchatka 'corner' can be accommodated by either a bend or a tear in the downgoing lithosphere (Davaille and Lees, 2004; Lees et al., 2000). Along the westernmost extent of the Aleutian Arc, the spreading direction of the Pacific Plate is essential parallel to the subduction zone. This rather rare subduction geometry is manifest by the NW striking 1000 km strike-slip Bering fault along the westernmost tail of the Aleutian Arc. The Kamchatka experiment shown in Figure 18 was composed of 15 broadband stations deployed on the Kamchatka Peninsula to examine the region of intersection between the Aleutian Arc and Kamchatka arc in detail. The results of the studies that emerged from that experiment suggest that the Pacific Plate does not simply 'bend' around the Aleutian–Kamchatka corner, but that subduction in Kamchatka is parallel to that in the Aleutians and that therefore a tear must separate the two slabs (Lees et al., 2000) (right-hand panel, Figure 18). This remarkable structure appears to give rise to a rare instance of slab melting as evidenced by both the seismic structures and presence of adakite-like magmas that have been erupted at the Aleutian–Kamchatka corner (Davaille and Lees, 2004). The Aleutian–Kamchatka corner may be one of the only places anywhere on the globe where a slab tear seems to be confirmed.

1.16.3.4 Active Continental Rifts

Continental rifts such as the East African and Baikal Rifts have been extensively studied through controlled-source experiments that both cross and traverse the rift valleys.

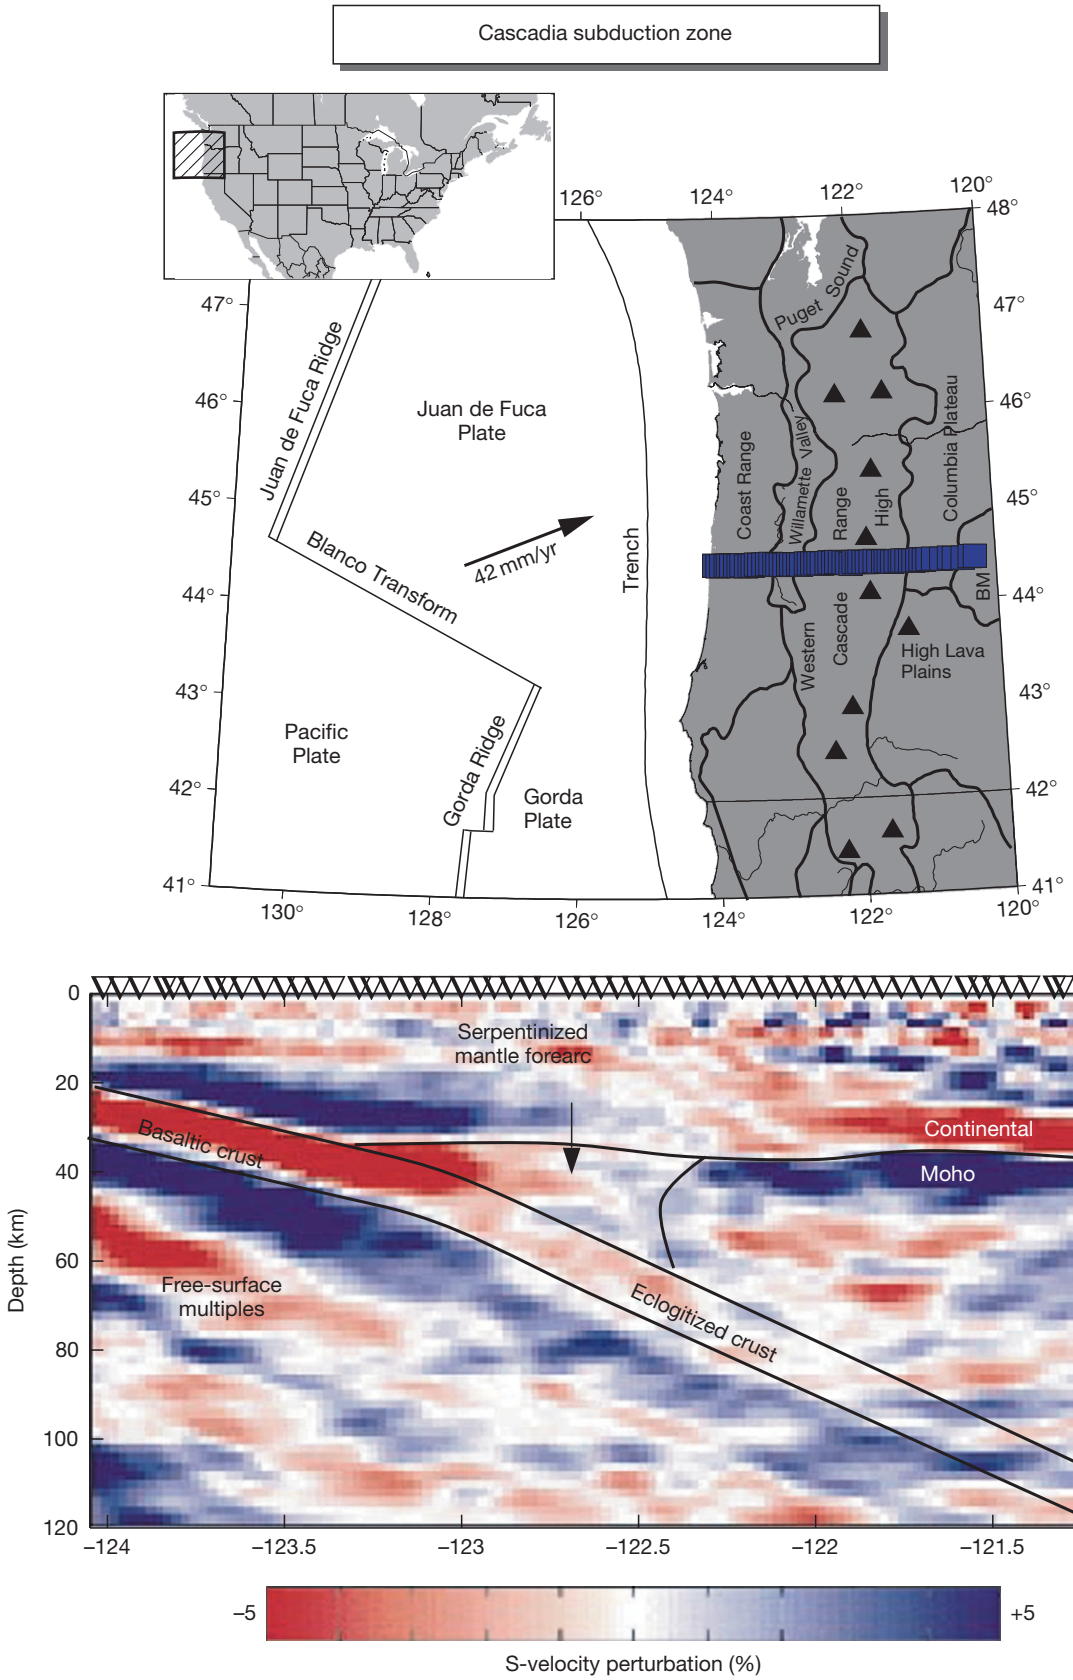

Figure 16 Imaging results from the 1993 Cascadia seismic experiment (CASC93; Nabelek et al., 1993) deployment of 44 broadband stations at ~5 km spacing from the Pacific coast across the Cascades into the Columbia Plateau and Blue Mountains (upper panel). The lower panel in an interpretive vertical cross section superimposed on the scattered wave inversion image of Rondenay et al. (2001). Copyright 2001, American Geophysical Union. Red indicates slow-velocity perturbations; blue, fast. See text for further discussion. Figure provided courtesy of Stephane Rondenay, MIT.

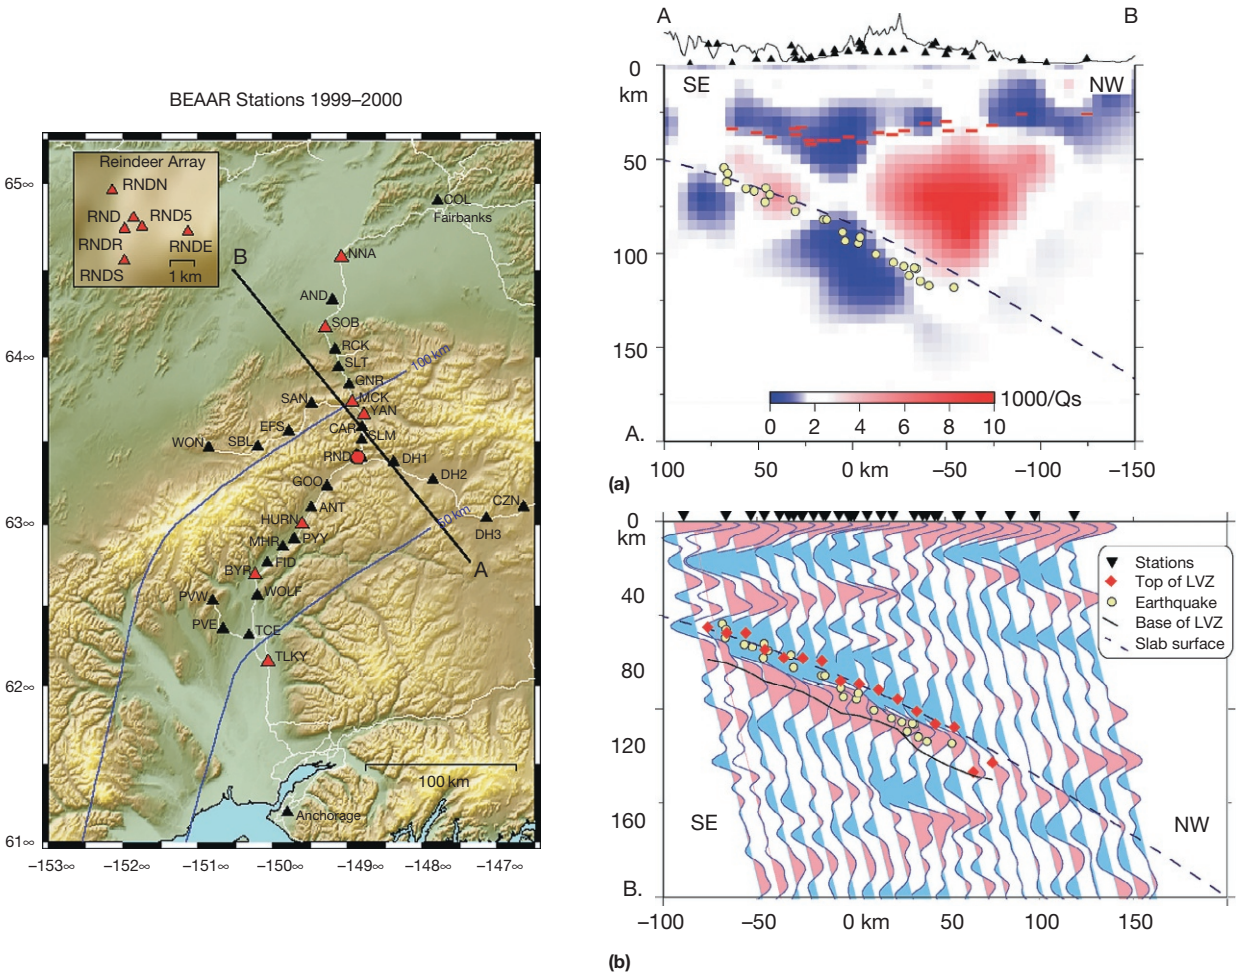

Figure 17 Broadband Experiment Across the Alaska Range (BEAAR). Map on the left shows station locations. Contours indicate depth to Wadati–Benioff zone. Top right figure is a vertical cross section of attenuation tomography along line A–B. Red, high attenuation; blue, low attenuation. Moho from receiver functions is indicated by red dashed line. The greatly reduced attenuation in the uppermost part of the mantle wedge suggests that material freezes out and no longer participates in the suprasubduction zone mantle wedge recirculation. The panel in the lower right shows the receiver function image with the inferred top of the slab indicated by a black dashed line. Earthquake hypocenters (relocated) are seen along the top of the slab at shallow depths but migrate into the slab with increasing depth. Figures courtesy of Geoff Abers. Modified from Abers GA, van Keken PE, Kneller EA, Ferris A, Stachnik, JC (2006) The thermal structure of subduction zones constrained by seismic imaging: Implications for slab dehydration and wedge flow. *Earth and Planetary Science Letters* 241: 387–397.

The Tanzanian broadband experiment extended into the East African Rift, but the deployment was sufficiently sparse that little could be determined other than that the region beneath the rift was very low velocity, as previously known (e.g., Weeraratne et al., 2003). A major broadband deployment was undertaken recently across the northern Ethiopian Rift where the rifting is transitional between continental and oceanic and where it forms the third arm of the Red Sea, Gulf of Aden rift triple junction (Bastow et al., 2005). Nearly 80 broadband instruments were installed in a 250 × 350 km area for a 16-month period, 2001–03, as part of the Ethiopia Afar Geoscientific Lithospheric Experiment (EAGLE) (**Figure 19**; Maguire et al., 2003). Bastow et al. (2005) obtained clear images of an approximately 75 km wide tabular low-velocity zone beneath the rift (**Figure 20**). The low velocities extend to 200–250 km beneath the Ethiopian Rift in the southern part of the region trending into the East African Rift of southern Ethiopia and northern Kenya. As the rift approaches the Afar Depression, the low-velocity anomaly at depths >100 km appears to broaden and merge with deeper low-velocity structures beneath the Afar Depression (Bastow et al., 2005).

1.16.4 Stable Platforms

1.16.4.1 Central and Eastern North America

Compared with western North America, few portable arrays have been deployed in stable central and eastern North America. Prominent among broadband deployments is the Missouri to Massachusetts Broadband Experiment (MOMA), the Lithoprobe/IRIS Abitibi–Grenville teleseismic experiment (ABI96), and the Florida to Edmonton (FLED) broadband experiment (Fischer et al., 1996; Rondenay et al., 2000). The northern extension of the FLED array ends in Edmonton,

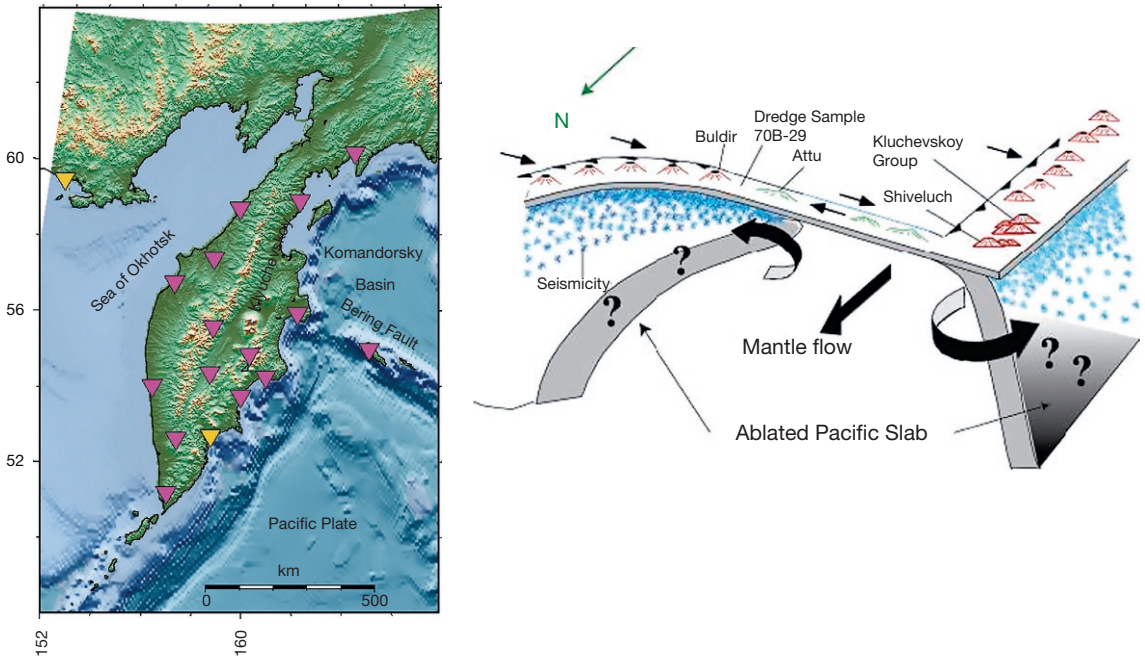

Figure 18 PASSCAL broadband deployment on the Kamchatka Peninsula to image the abrupt bend in subduction of the downgoing Pacific Plate (left-hand side panel). Image on the right is the interpretation of results showing slab separation with mantle flow through the corner region. Adapted from Lees JM, Brandon M, Park J, Levin V, Ozerov A, and Gordeev E (2000) Kamchatka: Edge of the plate. *IRIS Newsletter* 2000(1): 1–5.

Canada, just east of the Rocky Mountain Front (**Figure 1**). A recent deployment of nearly 60 broadband seismographs (the Canadian Northwest Experiment (CANOE)) picks up at Edmonton and continues as a Y-shaped transect to the NW (**Figure 1**). The array bifurcates into one transect across the Proterozoic and into the Slave craton and another that crosses the Canadian Rockies into the Yukon, a transect of nearly 4 Ga of geologic time (Bostock et al., 2005).

The MOMA deployment of 18 portable stations, anchored at each end by a permanent global station, is shown superimposed on the continent-scale model NA00 of van der Lee in **Figure 21** (van der Lee, 2002). Interstation spacing was about 100 km and the array operated for about 16 months. Receiver function determinations of crustal thickness along the profile show thickening of the crust beneath the Appalachians, thinning in the region of the Grenville Front and thickening again beneath the stable Proterozoic platform (Li et al., 2002). The root beneath the Appalachians, thicker than predicted for isostatic compensation, appears to reflect a 'densification' of the lower crust that Fischer (2002) had hypothesized is a common metamorphic process in older orogenic belts. Upper-mantle discontinuities from receiver functions observed beneath MOMA at depths around 270–280 km are visible in the eastern part of the array and have been interpreted as the (rarely observed) base of the asthenosphere beneath eastern North America (Li et al., 2002). Subsequent studies based primarily on extensive data from a handful of permanent stations in eastern United States suggest that the LAB is sharply defined, perhaps no more than 10–12 km in vertical extend, beneath the Phanerozoic (Rychert et al., 2005).

Van der Lee (2002) analyzed S waves and fundamental-mode surface waves along the strike of the array and combined those data with previous data used to develop the North American model NA95 to obtain high-resolution constraints on crustal thickness and S-wave velocity beneath the MOMA array as shown in **Figure 21**. The lower panel of **Figure 21** contains the new velocity structure in cross section and in terms of velocity perturbations. The thin dashed black line in that figure is presumed to represent the base of the seismic lithosphere and the white line the thermal thickness of the lithosphere as computed by Goes and van der Lee (2002). The lithospheric upper mantle is poorly resolved beneath Phanerozoic North America despite receiver function evidence of a sharp LAB beneath that region (Rychert et al., 2005).

Measurements of anisotropy along the MOMA array have produced a number of important results. Fouch et al. (2000) modeled the shear-wave splitting as asthenospheric shearing due to plate motion as the asthenosphere flowed under and around the continental keel of stable North America in response to the SW absolute motion of North America. They found no evidence for lithospheric anisotropy beneath the Proterozoic platform. Subsequent studies using Rayleigh and Love surface waves suggest a shallow lithospheric layer with significant 'radial' anisotropy (Gaherty, 2004). SKS splitting and surface waves indicate that azimuthal anisotropy is present primarily in the subcontinental asthenosphere as it deforms in response to plate motion.

The Abitibi–Grenville teleseismic experiment (ABI96) involved a 6-month N–S deployment of 28 broadband stations (Rondenay et al., 2005). Crustal thickness transitions abruptly near the Grenville Front, from 40–45 km in the Proterozoic south to the more characteristically thin (35 km) crust of the Archean craton in the north (Rondenay et al., 2000, 2005). Unlike results from MOMA, shear-wave splitting reveals a

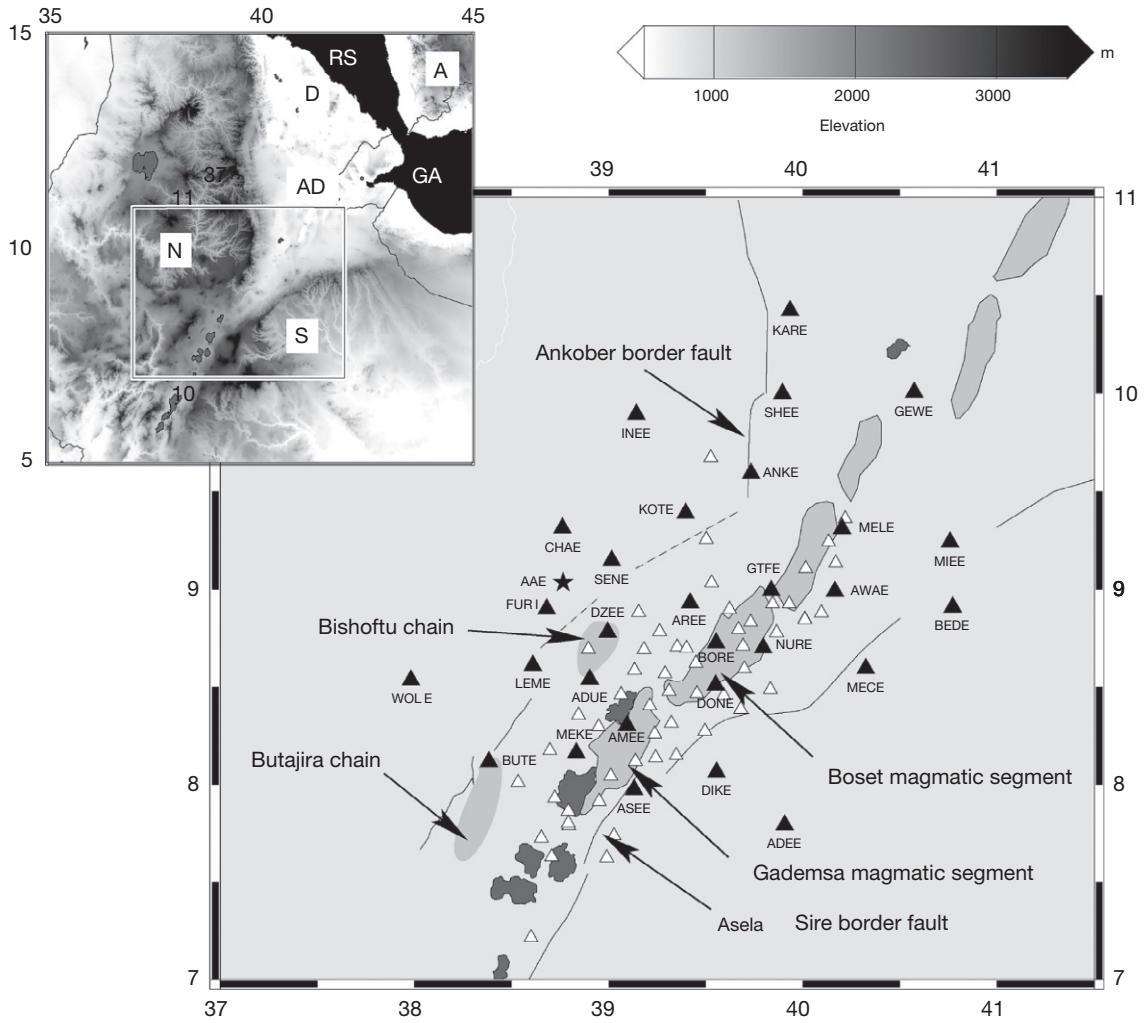

Figure 19 Station locations for the EAGLE broadband experiment, arrayed along the Ethiopian Rift transitional into the Red Sea (see text). Filled triangles are for phase I of the experiment; open triangles for phase II. Stations were deployed for a total of 2 years (2001–03). On inset, RS denotes Red Sea, GA denotes Gulf of Aden, A denotes Arabian Plate, AD denotes Afar Depression, D denotes Danakil microplate, N denotes Nubian Plate, and S denotes Somalian Plate. Reproduced from Bastow ID, Stuart GW, Kendall JM, and Ebinger C (2005) Upper-mantle seismic structure in a region of incipient continental breakup: Northern Ethiopian rift. *Geophysical Journal International* 162: 479–493, with permission from Blackwell Publishing.

monotonous pattern of dominantly E–W fast directions and relatively small delay times around 0.5 s, with no transition across the Grenville Front (Figure 22). The fast directions along the Abitibi–Grenville line tend to be oriented at a relatively high angle to absolute plate motion and accordingly have been interpreted as due to fossil anisotropy in the lithosphere (Fouch and Rondenay, 2006; Rondenay et al., 2000). A summary of fast polarization directions and magnitude of the delay times measured over several experiments for central and eastern North America is shown in Figure 22.

1.16.4.2 Australia

The Australian continent is particularly well suited for seismic investigations of variation in lithospheric structure between Archean, Proterozoic, and Phanerozoic terranes. The southwestern quarter or so of the continent is underlain by several Archean crustal blocks. The vast central and west-central part of Australia is Proterozoic in age and the eastern third of the country is Phanerozoic. The so-called Tasman line, the precise location of which is still disputed but which shows up repeatedly in discussions of Australian terranes, divides the Precambrian terranes from the Phanerozoic (e.g., Simons et al., 1999).

Over the past two decades, the Australian continent has been instrumented in a sparse but systematic grid of portable broadband stations, the most prominent of which composed a succession of deployments known as SKIPPY (1993–96). SKIPPY was an innovative experiment in which a single array of approximately 10–12 stations was 'skipped' kangaroo style across the continent in six major deployments (van der Hilst et al., 1994). It was specifically designed to capitalize on the substantial arc-related regional seismicity to the east and north of the continent. The SKIPPY array has since been complemented by a number of regional temporary arrays deployed to examine specific regions in more detail (Fishwick et al., 2005). The map figure in the upper left panel of Figure 23

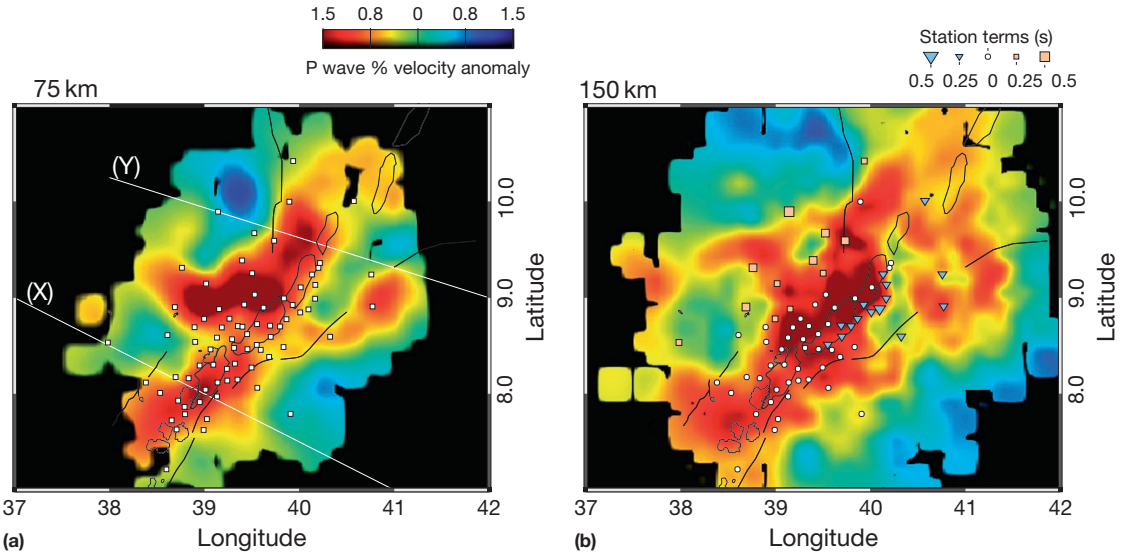

Figure 20 Horizontal depth slices of 3-D tomographic images of P-wave perturbations beneath the Ethiopian Rift as shown in **Figure 19**. Extreme low velocities are shown beneath the broad area of the rift axis to depths of at least 250 km. Modified from Bastow ID, Stuart GW, Kendall JM, and Ebinger C (2005) Upper-mantle seismic structure in a region of incipient continental breakup: Northern Ethiopian rift. *Geophysical Journal International* 162: 479–493, with permission from Blackwell Publishing.

shows broadband deployments superimposed on the geologic outline map of Australia. As few of these deployments are sufficiently dense for high-resolution body wave tomography, the station and source geometry has been most amenable to surface wave tomographic analysis and to receiver function crustal thickness determinations (e.g., Clitheroe et al., 2000; Fishwick et al., 2005; Simons et al., 1999). Until recent work, when relatively dense arrays were installed in the Archean SW of Australia (e.g., Fishwick et al., 2005), surface wave coverage had been most dense in the eastern part of the continent and least dense in the southwest.

Lithospheric imaging beneath Australia is particularly revealing because the instruments and the kind of data used are relatively uniform across the entire continent, making direct comparisons between provinces of different geologic ages possible. Fishwick et al. (2005) integrated data from earlier portable broadband arrays (e.g., Simons et al., 1999) with data compiled from recent deployments in western Australia to produce lithospheric images of consistent quality across the continent (**Figure 23**). The results in **Figure 23** are derived by PWI but with several different starting models as to improve the recovery of the averaged 1-D path model for the significantly different propagation path structures encountered (e.g., oceanic vs. continental) and have been updated since the Fishwick et al. (2005) paper. The results reveal a remarkably wide range in shear velocities, in excess of 15% even at 150 km depth, beneath the Australian continent. At 100 km depth, high velocities are observed throughout most of the continent including parts of Australia well east of the Tasman line. These higher velocities beneath even the Phanerozoic terranes are interpreted to represent thick lithosphere. Lower velocities are seen at 100 km depth only along the easternmost part of the continent. The anomalously low velocities at 100 km depth along the eastern margin of the continent appear to be correlated with zones of Neogene volcanism as observed earlier by Zielhuis and van der Hilst (1996). Most of the observed velocity contrast appears to be due to temperature variations, and based on the work of Faul and Jackson (2005), Fishwick et al. (2005) concluded that a temperature contrast of ~600 °C could account for the velocity differences between the ocean basins and the oldest parts of the continent at 150 km depth. High-velocity material in the upper mantle beneath western Australia extends to at least 150 km beneath the Archean cratons. High-velocity material is not seen to depths greater than about 150 km beneath the small Pilbara Craton, but is observed to depths of at least 250 km beneath the Yilgarn Craton to the SW and the Kimberley Craton to the NW. In general, the higher velocities at greater depths (>200 km) beneath Australia do not correlate simply with age terranes.

The crustal structure beneath Australia has been investigated primarily through receiver function methods based on some of the same station data as those used for the surface wave inversion studies discussed earlier in the text (Clitheroe et al., 2000). The crust beneath the undisturbed parts of the western cratons averages about 35–40 km thick, although the crust as thin as 25–30 km is seen beneath parts of the Archean-age Yilgarn and Pilbara Cratons and thicker crustal sections abut the Yilgarn to the west. The Moho tends to be sharp beneath the cratonic interiors but more gradational near terrane boundaries (Reading et al., 2003). The vast Proterozoic interior of the Australian continent is underlain by crust mostly 40–55 km thick, with a relatively transitional Moho. The thickest crustal section yet found in all of Australia is beneath the Amadeus Basin in central Australia, low lying despite a maximum crustal thickness of 61 km. The eastern third of Australia (east of the inferred Tasman line) is composed primarily of the late Phanerozoic Tasman orogen (Clitheroe et al., 2000), where a complex of accretionary terranes was assembled against the Proterozoic continental nucleus (Betts et al., 2002). The thicker crust of the Proterozoic of central Australia

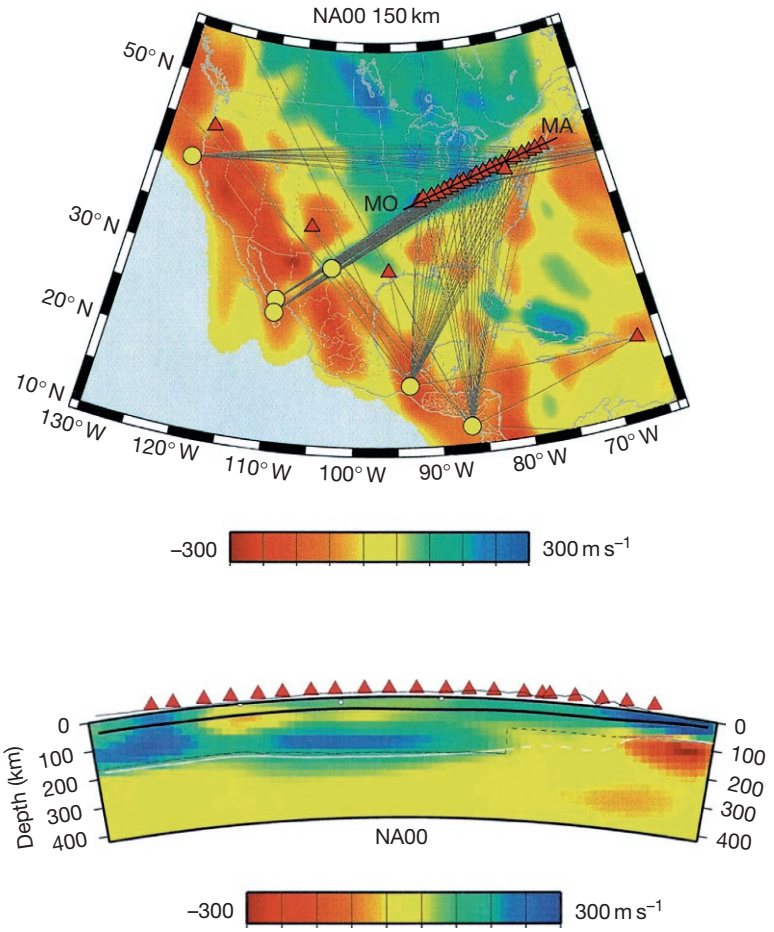

Figure 21 Missouri to Massachusetts (MOMA) broadband array (red triangles). Top figure shows map of the array and the events plus great circle propagation paths (gray lines) used for partitioned waveform inversion superimposed on the 3-D North America model NA00 of van der Lee at a depth of 150 km (van der Lee, 2002). The black line through the stations is the trace of the vertical cross section shown in the bottom panel. The bottom panel is a vertical cross section illustrating velocity perturbations showing a clear high-velocity lithosphere beneath stable continent length of the array. The thin black line represents the base of the lithosphere (as defined by van der Lee, 2002) and the thin white line the thermal thickness of the lithosphere based on Goes and van der Lee (2002). The slightly low-velocity channel beneath the lithosphere is still very high velocity (4.55 km s^{-1}) relative to the typical LVZ of the ocean basins. Adapted from van der Lee S (2002) High-resolution estimates of lithospheric thickness from Missouri to Massachusetts, USA. *Earth and Planetary Science Letters* 203(1): 15–23.

thins east of the Tasman line to a relatively uniform crust of about 35 km thick that is characterized by a sharp Moho. The abrupt shift in crustal thickness and Moho structure from thick Proterozoic to thin Phanerozoic is in contrast with images of mantle lithosphere, where the Tasman line is not at all well defined (**Figure 23**; Fishwick et al., 2005).

1.16.4.3 South America

Southeastern Brazil is by far the most thoroughly studied part of stable South America (e.g., Schimmel et al., 2003, where portable broadband arrays have been installed in a SKIPPY-like expanding and migrating observational network since 1992. The arrays, with up to 15 stations operating at one time, total 45 stations over an area about 1000 × 1700 km (**Figure 24**). The region encompasses the Archean São Francisco Craton, the Paraná Basin – a massive flood basalt province c.130 Ma – and its adjoining margins of Cretaceous alkaline intrusives. The most remarkable, and most controversial, finding from the tomographic imaging in this region is the discovery of an apparent 'fossil' Paraná plume at depths 200–600 km in the upper mantle beneath the Paraná Basin (VanDecar et al., 1995) (bottom image, **Figure 24**). Tomographic images of the upper mantle also show that the keel of the Archean São Francisco Craton extends to depths of 200–300 km. The lithosphere is considerably thinned in the region of the postrifting Late Cretaceous alkaline intrusives that cluster locally throughout much of SE Brazil, particularly around the margins of the Paraná Basin and the São Francisco Craton (Schimmel et al., 2003). Anisotropy beneath that same region of SE Brazil as determined by SKS splitting appears to be controlled largely by preexisting lithospheric structures rather than mantle flow (James and Assumpção, 1996).

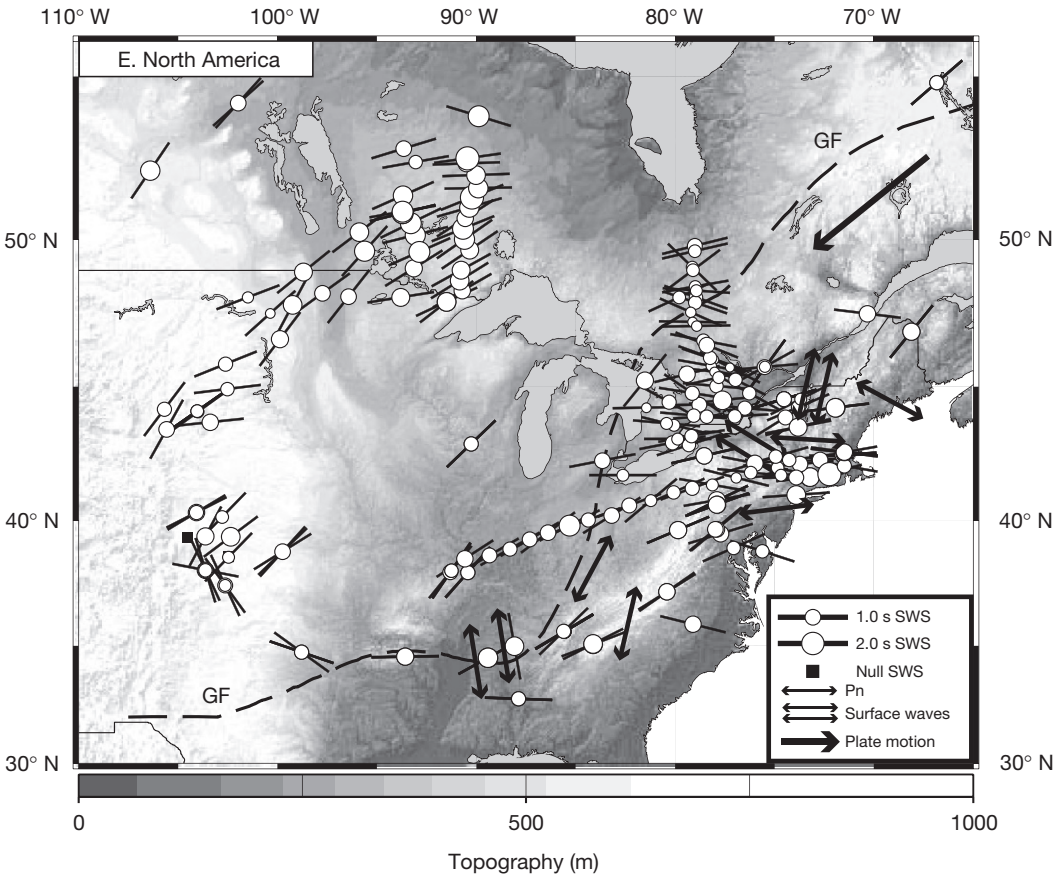

Figure 22 Summary of published shear-wave splitting results for eastern North America. Black bars indicate fast direction of anisotropy. The size of circle is proportional to splitting delay time as shown in the inset. Anisotropy measurements from surface waves and Pn measurements are represented by double black arrows. GF denotes Grenville Front. Reproduced from Fouch MJ and Rondenay S (2006) Seismic anisotropy beneath stable continental interiors. *Physics of the Earth and Planetary Interiors* 158: 292–320.

1.16.4.4 Antarctica

Despite extreme cold, lack of sunlight for solar power half of the year, little infrastructure, and other serious logistical challenges, portable broadband experiments on the continent of Antarctica have not been wanting. Efforts to operate portable seismic instruments have been underway for well over a decade, and new technologies have been developed to operate in extreme arctic conditions. Thanks largely to those efforts, as well as continuing support from the permanent facilities that the NSF Polar Program maintains in Antarctica, an ambitious array experiment was undertaken recently to map the contrasting crustal and upper-mantle structures along a transect across the West Antarctic Rift System, the Transantarctic Mountains, and the East Antarctic Craton (Figure 1). The Transantarctic Mountain Seismic Experiment (TAMSEIS) involved a deployment of 41 broadband seismometers that recorded from 2000 to 2003 under extraordinarily difficult operating conditions (Figure 1). Analysis of the data collected from the TAMSEIS project is highly preliminary, but results to date reveal high velocities in the mantle beneath the (old) East Antarctic Craton and a zone of low velocities that extends to 200 km beneath the (young) Transantarctic Mountains and NNE beneath McMurdo Sound and the Ross Sea (Watson, 2005). The area of McMurdo Sound includes Mt. Erebus, an active Antarctic volcano and the highest peak in the Transantarctic Mountain belt.

1.16.5 Archean Cratons

Archean cratons, the ancient cores of continents, are prime targets for portable array seismology. Archean cratons exhibit a number of distinctive features that set them apart from all younger continental structures. Notably, cratons are underlain by a thick mantle root (tectosphere; Jordan, 1975) that is both chemically and physically distinct from the rest of the mantle, including other continental lithosphere, suggesting formation by processes unique to Archean time. The refractory tectospheric root is now known to be ancient, composed dominantly of highly depleted peridotites with low normative density and high seismic velocities (Boyd and McCallister, 1976; Boyd and Mertzman, 1987; James et al., 2004; Jordan, 1979) and at least 200 km thick (e.g., Bruneton et al., 2004; Grand, 1994; James and Fouch, 2002; James et al., 2001, 2004; Jordan, 1975; Lerner-Lam and Jordan, 1987; Van der Lee and Nolet, 1997; Zhao et al., 1999).

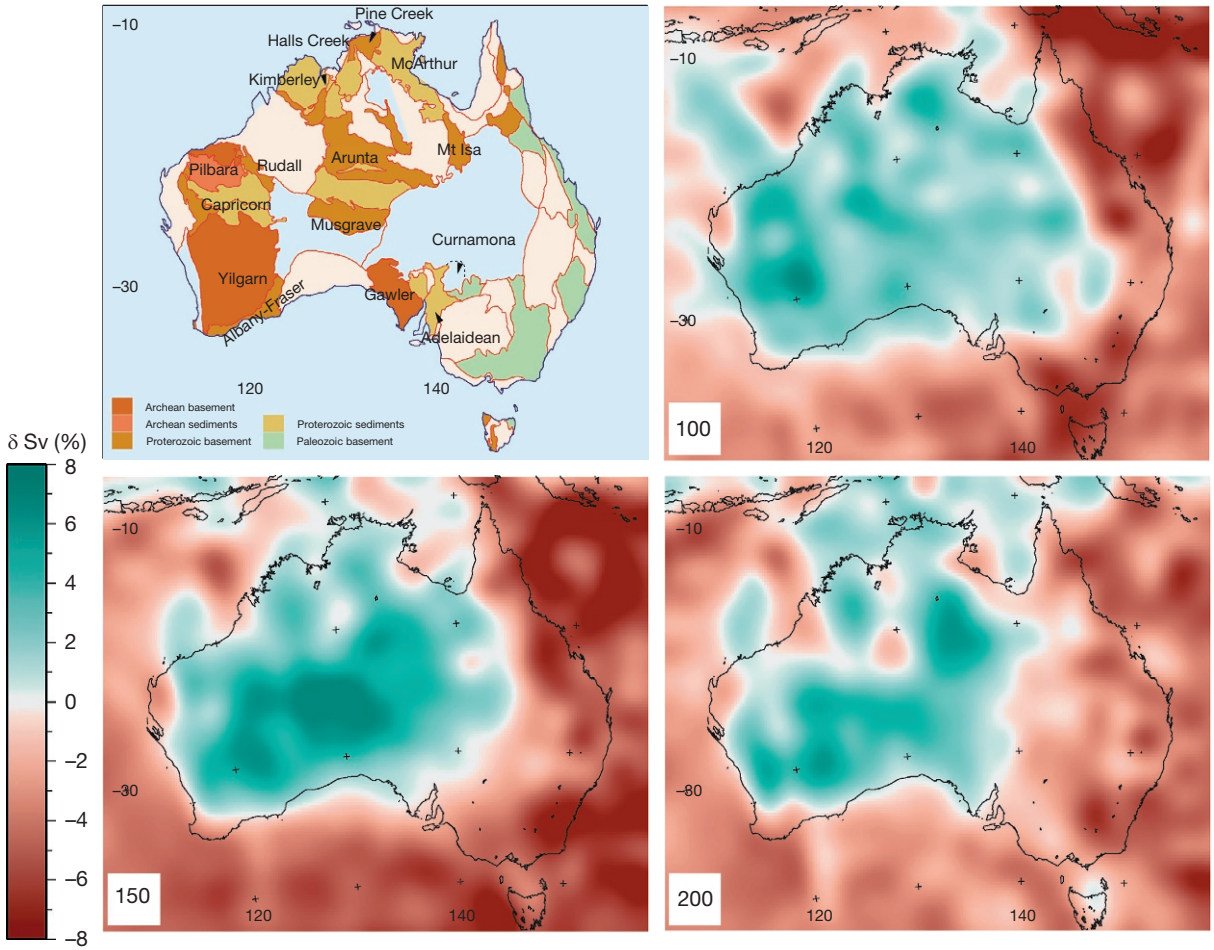

Figure 23 Horizontal depth slices of S-wave tomographic images beneath Australia. Velocity perturbation color scale is shown on the left, with perturbations referenced to global model AK135. The upper left panel shows locations of stations deployed as part of broadband experiments, from 1993 to the present, superimposed on principal geologic units. Modified from Fishwick S (2005) Contrasts in lithospheric structure within the Australian craton – Insights from surface wave tomography. *Earth and Planetary Science Letters* 231: 1630176.

The distinctive character of cratonic mantle and the nature of the crust and the crust–mantle boundary distinguish Archean from post-Archean terranes. Paradoxically, the Archean crust appears to be both thinner and less mafic than post-Archean crust (Griffin and O'Reilly, 1987; James et al., 2003; Rudnick, 1995). Moreover, the Archean Moho is characteristically sharper than that beneath younger terranes. These observations, together with the unique character of the cratonic root, suggest that the processes of craton formation, or the physical conditions that controlled those processes, differed in important ways from continent-forming processes in post-Archean times. Passive array studies are largely aimed at understanding the circumstances and mechanics of early continental formation.

1.16.5.1 Southern Africa

The Southern African Seismic Experiment (Figure 25), part of the multidisciplinary and multinational Kaapvaal Project, is the largest of the broadband array experiments undertaken to probe the anatomy of Archean cratons and their relationship to adjacent Proterozoic mobile belts (Carlson et al., 1996; James and Fouch, 2002; James et al., 2001). A nearly continuous Archean geologic record, from 3.6 to 2.6 Ga, is preserved within the Kaapvaal craton (e.g., De Wit et al., 1992). A significant area of the region covered by the seismic array, both on and off craton, has been perforated by thousands of Cretaceous kimberlite pipes from which a wealth of crustal and mantle xenoliths were erupted, some from depths in excess of 200 km (Gurney and Harte, 1980). The chemical and mineralogical compositions of mantle xenoliths provide some of the very best constraints that seismologists have for verifying seismic images of the deep continental lithosphere and relating them to actual rocks in the mantle (e.g., James et al., 2004).

Fifty-five portable broadband seismic stations were deployed at 82 sites from April 1997 to July 1999 in a roughly 100 km grid along a NNE–SSW transect about 1800 km long by 600 km wide in southern Africa (Figure 25). The experiment was augmented by a 6-month deployment of 32 telemetered broadband stations installed in a dense ($\sim 65 \times 50$ km) array in the vicinity of Kimberley, South Africa, in the heart of the undisturbed Kaapvaal craton (Figure 25).

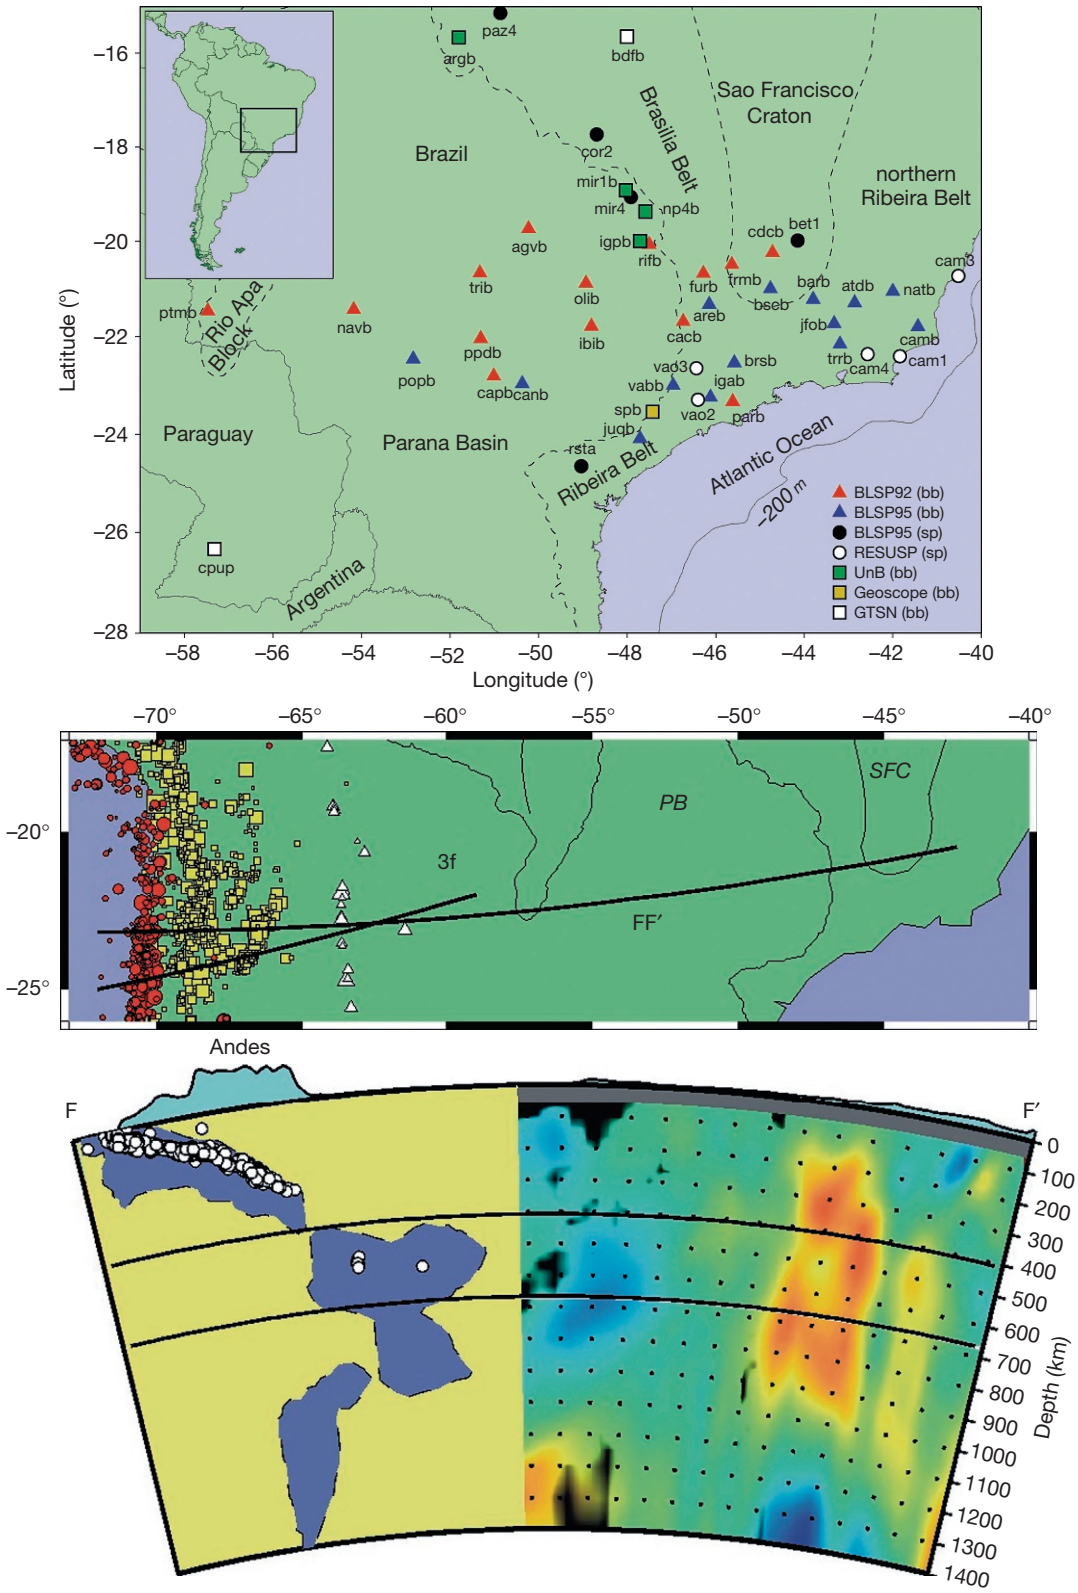

Figure 24 Map showing locations of successive broadband deployments in SE Brazil, from 1992 to the present (Schimmel et al., 2003). The bottom panel is split, with the left-hand side showing the high wavespeed (blue) anomalies adapted from Engdahl et al. (1995) and the right-hand side showing P-wave body wave tomography from the Brazilian arrays. The most prominent feature of the P-wave body wave image shown is the low-velocity anomaly that extends vertically beneath the Paraná Basin. VanDecar et al. (1995) speculated that the anomaly represented a fossil plume conduit for the Paraná flood basalts. Adapted from Schimmel M, Assumpcao M, and VanDecar JC (2003) Seismic velocity anomalies beneath SE Brazil from P and S wave travel time inversions. *Journal of Geophysical Research* 108(B4): 1–15. http://dx.doi.org/10.1029/2001JB000187.

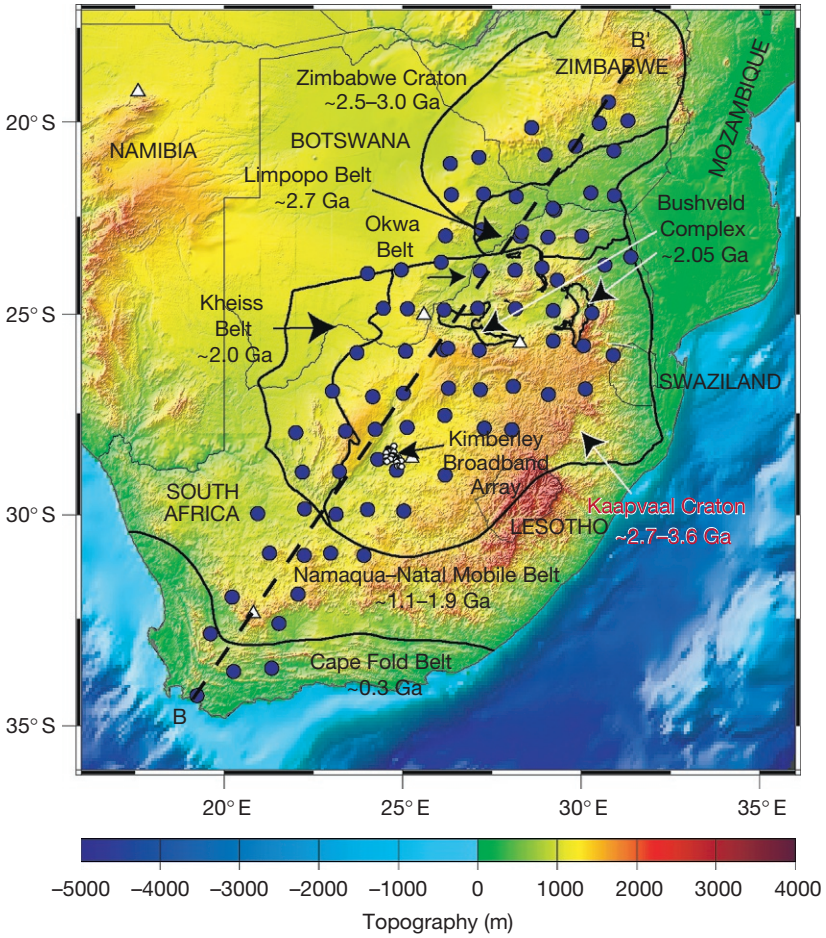

Figure 25 Map showing station locations, topography, and principal geologic provinces in the region of Kaapvaal Project within southern Africa. Eighty-two broadband stations were occupied over a 2-year period from 1997 to 1999 in South Africa, Botswana, and Zimbabwe. The Kimberley array consisted of 31 broadband stations deployed in an area approximately 60 × 40 km. In addition, three GSN broadband stations (white triangles) are located in the region and their data are incorporated in the tomographic analysis. The array extends from the Cape Fold Belt in the south, through the Proterozoic Namaqua–Natal Mobile Belt, across the Kaapvaal craton and Bushveld Province, through the Archean Limpopo Mobile Belt, and into the Zimbabwe craton.

1.16.5.1.1 Mantle tomographic images

Tomographic results (Fouch et al., 2004; James and Fouch, 2002; James et al., 2001) show that high-velocity mantle roots extend locally to depths of at least 250 km beneath undisturbed Archean craton, with no comparable root structures beneath post-Archean terranes (**Figure 26**). While only P-wave velocity structure is shown in **Figure 26**, mantle velocities in both P and S waves are remarkably consistent (Fouch et al., 2004; James et al., 2001). High velocities in both P and S waves coincide with the interiors of the Kaapvaal and Zimbabwe cratons. Excepting regions of disrupted craton (as beneath the 2.05 Ga Bushveld Province), the tectospheric root attains a thickness of ~200–250 km almost everywhere beneath the cratons, including the Archean Limpopo Mobile Belt. The most remarkable 'disrupted' feature of the Kaapvaal craton is seen in the low velocities in the mantle beneath the Bushveld Complex, the largest layered intrusion in the world. In contrast, the mantle structure of the Archean Limpopo Mobile Belt, a collision zone between the Zimbabwe and Kaapvaal cratons, does not differ significantly from that of the adjacent cratons. Neither body nor surface wave analyses have produced evidence of a significant low-velocity zone beneath the cratonic keel (Freybourger et al., 2001; James et al., 2001; Larson et al., 2006; Ritsema and van Heijst, 2000; Zhao et al., 1999). Recent surface wave results for the southern Kaapvaal (Larson et al., 2006) give absolute S-wave velocities that are consistent with the velocity-depth structure estimated from Cretaceous-age mantle xenoliths derived from the cratonic root (James et al., 2004).

The Proterozoic Namaqua–Natal Mobile Belt, the remnants of a major N–S convergent margin along the Kaapvaal that may have extended as far north as the Zimbabwe craton (De Wit et al., 1992), is characterized by velocity perturbations uniformly lower than those observed beneath the craton. The lower velocities are in keeping with the observation that the off-craton Proterozoic mantle tends to be somewhat more fertile (higher Fe) than that of the adjacent craton, as well as slightly warmer (Carlson et al., 2000; James et al., 2004; Pearson et al., 2002).

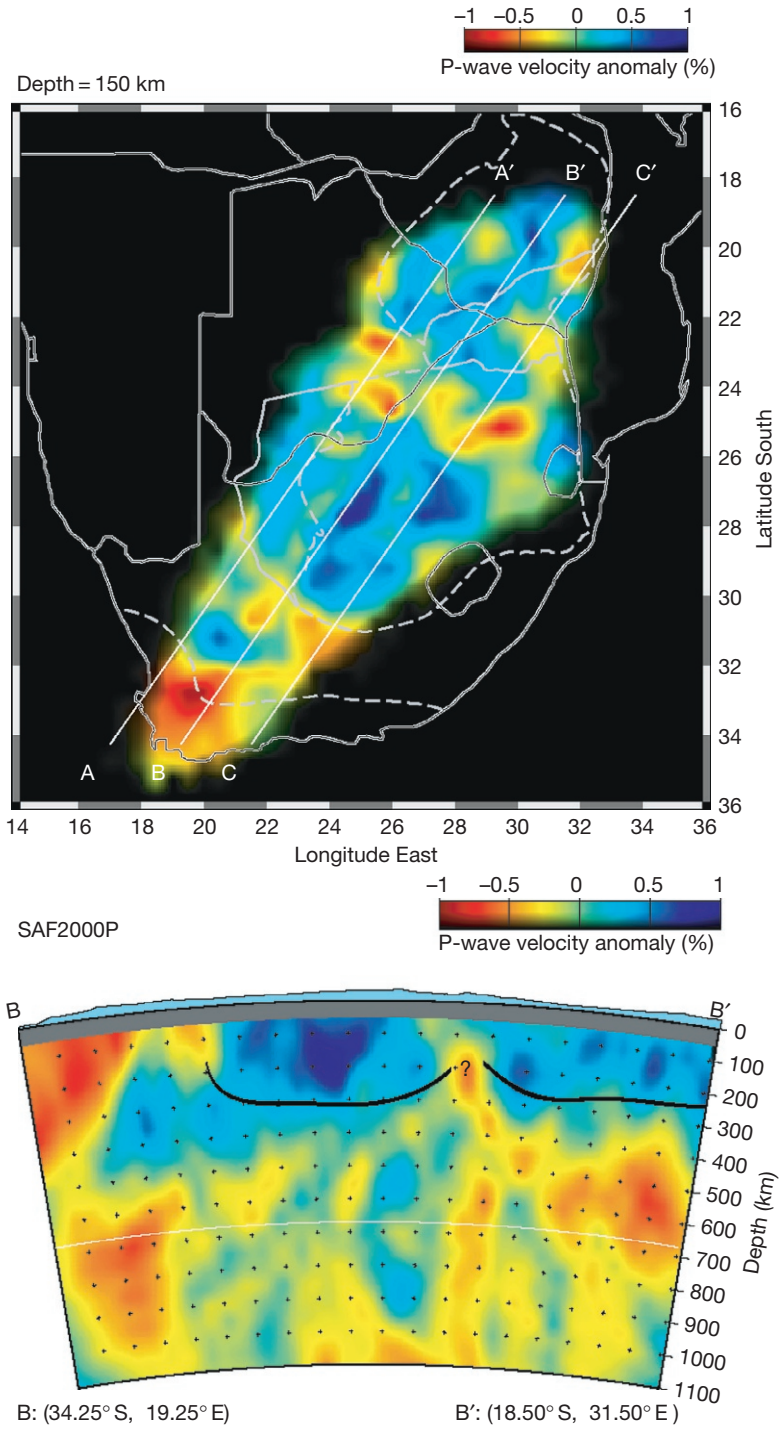

Figure 26 Relative P-wave velocity perturbations from inversion of seismic delay times with overlaid geologic province outlines. Adapted from James DE and Fouch MJ (2002) Formation and evolution of archaean cratons: Insights from southern Africa. In: Ebinger C, Fowler CMR, and Hawkesworth CJ (eds.) *The Early Earth: Physical, Chemical and Biological Development*, pp. 1–26. London: Geological Society of London. Velocity anomaly scale ranges from deep blue (1% fast) to deep red (1% slow). Top panel is map (horizontal section) view of velocity perturbations at 150 km depth. Kimberlite locations for xenoliths used in this study are marked by square symbols. Lower panel is a cross section along line B–B′ of the horizontal section. Topography, scaled by a factor of 20, is shown in light green. Tectospheric root can be seen beneath the southern Kaapvaal craton extending to a depth of nearly 300 km. The region of seismic low velocities in the uppermost mantle underlies the Bushveld Province.

1.16.5.1.2 Crustal thickness and Moho structure beneath southern Africa

Strong variations in crustal thickness based on receiver functions reveal significant differences in the nature of the crust and the crust–mantle boundary between Archean and post-Archean geologic terranes (**Figure 27**; Nguuri et al., 2001). Stations located within undisturbed Kaapvaal or Zimbabwe craton typically have sharp, large amplitude depth images for the Moho, similar to those observed for other Archean terranes (e.g., Clitheroe et al., 2000). In contrast, stations within post-Archean and modified cratonic regions typically exhibit poorly defined Ps-converted phases. Moreover, the crust beneath post-Archean and modified cratonic regions is in almost all cases thicker than that beneath the cratons. Throughout the broad region of the Bushveld and Okwa/Magondi terranes (**Figure 25**), the Archean craton has been overprinted by tectonomagmatic events of Proterozoic age (e.g., Carney et al., 1994; Shirey et al., 2001) and the effects on crustal structure have been profound. The crust thickens and the Moho signature degrades, for example, passing from undisturbed craton into the Bushveld Province and between undisturbed Zimbabwe craton into the Magondi belt. The change in crustal structure is consistent with the evidence from tomographic imaging for major disruption in the uppermost mantle beneath the entire region (**Figure 26**).

Depth images for the northern and southern marginal zones of the collisional Limpopo Mobile Belt are typical of the adjacent cratonic structure, both in the character of the Ps conversion and in crustal thickness (**Figure 27**). The central Limpopo Mobile Belt, site of maximum deformation during the collision of the Kaapvaal and Zimbabwe cratons in the Archean, displays broad, poorly defined Ps images indicative of structurally complex Moho and with depth maxima occurring between 40 and 53 km. As with the Bushveld, the relatively thick crust beneath the Limpopo appears not to be isostatically compensated at the surface, suggesting 'densification' of the deep crustal root (Fischer, 2002).

Kimberley array. The 31-station telemetered broadband Kimberley array deployment comprised a dense grid over an area of about 65×50 km (**Figure 25**) near Kimberley, South Africa, in the south-central region of the Kaapvaal craton. Analysis of both teleseismic and local events recorded on the Kimberley broadband array reveals a remarkably uniform crustal structure beneath the array: (1) The cratonic crust is uniformly thin (about 35 km) and has a low average Poisson's ratio ($\sim$0.25, $V_p/V_s \approx 1.73$). (2) The Moho is a sharp discontinuity, with a crust–mantle transition less than about 0.5 km beneath the array (James et al., 2003; Niu and James, 2002).

The low Poisson's ratio of 0.25 ($V_p/V_s = 1.73$) for the crustal average and an inferred density of 2.86 gm cc^{-1} for the lowermost crustal rocks highlight one of the great dilemmas of Archean crustal composition (e.g., James et al., 2003; Rudnick, 1995). If the continental crust was derived from a hotter mantle in the Archean, why is the crust beneath the Kaapvaal less mafic than that beneath adjacent Proterozoic mobile belts, where the lower crust is mafic? Niu and James (2002) suggested that the present composition of the Kaapvaal crust may be explained as the result of extensive melting of the lower crust during ultrahigh-temperature metamorphism associated with a craton-wide tectonomagmatic event in the Late Archean. Layering and flow associated with the crystallization of melt in the lowermost crust is one possible means for producing both flat Moho and sharp Moho, as well as the evolved rock compositions inferred from the seismic data (James et al., 2003; Niu and James, 2002).

1.16.5.2 Passive Array Studies of Other Cratons

Relatively small experiments in the Slave and Tanzanian cratons are of particular interest. The Slave craton in northern Canada is small in area but contains some of the oldest rocks on Earth and a wealth of diamonds. Reconnaissance studies of the Slave based on 13 broadband stations deployed over a 2-year period in the 1990s showed somewhat similar structures to those seen in the Kaapvaal, including a relatively thin crust and a tectospheric root, the depleted material of which apparently does not extend to depths as great as seen in the Kaapvaal (Bank et al., 2000). Data from the Tanzanian Broadband Seismic Experiment, composed of 20 stations deployed in 1994–95 across the Tanzanian craton and adjacent rifted mobile belts (Ritsema et al., 1998), have been analyzed in a number of independent studies. The deep lithospheric structure of the cratonic root remains somewhat in doubt. Body wave tomography indicates that the high-velocity tectosphere extends to a depth of at least 200 km beneath the craton (Ritsema et al., 1998). More recent surface wave studies, however, appear to indicate a thinner cratonic lithosphere ($\sim$150 km), the base of which may have been degraded by a rising plume associated with the East African Rift system (Weeraratne et al., 2003). The presence of adjacent rift zones with extremely low mantle velocities extending to considerable depth, however, makes the surface wave results difficult to interpret, as the poor lateral resolution inherent in surface wave tomography renders cross contamination of structures a major concern. Crustal structure is similarly controversial. Julia et al. (2005) interpreted results from joint receiver function/surface wave inversion of the broadband data to imply a mafic lower crust beneath the craton. This conclusion is contrary to that reached by much the same group of authors in a previous paper (Last et al., 1997), based on approximately the same data, where the East African crust was judged more felsic than the Precambrian crust elsewhere.

A large-scale multinational seismic experiment within the Baltic (Fennoscandian) Shield (SVEKALAPKO) focused on the lithospheric and asthenospheric structure of the East European Craton to a depth of about 400 km. The dense array across mostly Archean and Proterozoic terranes consisted of 143 stations, including 40 broadband and 88 short-period portable stations deployed for about 9 months, 1998–99 (Bruneton et al., 2004; Sandoval et al., 2003, 2004). Results from body wave tomography (Sandoval et al., 2004) have been mixed and difficult to interpret. High mantle velocities extend to depths of at least 250 km, but they trend seamlessly across both Archean and Proterozoic terranes, with no clear evidence for a distinct cratonic root beneath the Archean. Surface wave tomography with good resolution to a depth of about 150 km reveals strong velocity variations that are attributed to varying composition (rather than temperature), but here also mantle velocities do not differ significantly beneath Archean and Proterozoic terranes (Bruneton et al., 2004).

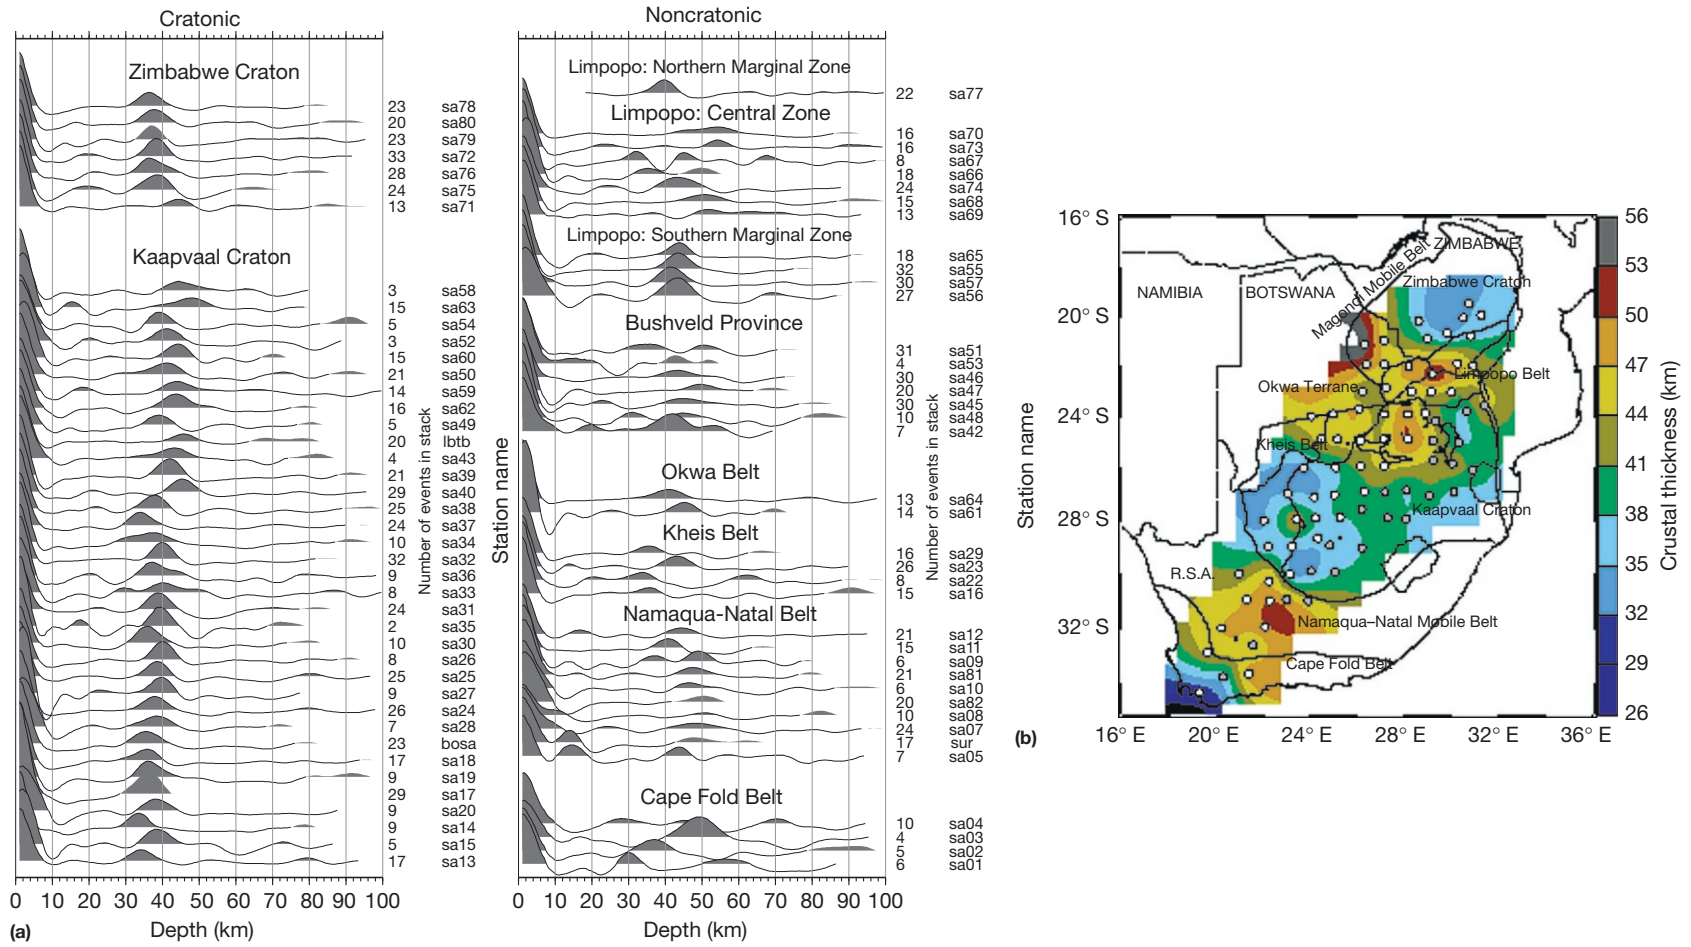

Figure 27 (a) Receiver function depth images for southern Africa, arranged by geologic province. The number of events in the stack and the station name for each trace are shown to the right of the trace. The dominant signal on most of the depth images is the P-to-S conversion (Ps) from the Moho. Relatively thin (35–40 km) crust and sharp, well-defined Ps Moho conversions tend to be associated with undisturbed craton. Ps arrivals associated with disturbed regions of the craton and post-Archean terranes tend to be more diffuse and of smaller amplitude. (b) Color-coded contour map of depth to Moho beneath the southern African array based on receiver function depth images. Crustal thickness color scale is shown on the right. Thin crust tends to be associated with undisturbed areas of the craton, particularly in the southern and western parts of the Kaapvaal craton and in the Zimbabwe craton, despite a regional elevation above 1100 m (3500 ft). Recent work by Webb suggests that much of the gravity compensation for excess elevation in the craton comes from low-density mantle (Webb, 2006). Reproduced from Nguuri T, Gore J, James DE, et al. (2001) Crustal structure beneath southern Africa and its implications for the formation and evolution of the Kaapvaal and Zimbabwe cratons. *Geophysical Research Letters* 28(13): 2501–2504.

1.16.6 Seismic Constraints on Composition and Temperature of the Continental Lithosphere

The range of seismic velocities in the continental lithospheric mantle indicates that the most abundant rock type is peridotite and that the major variations in seismic velocity are produced by temperature (e.g., Carlson et al., 2005, **Chapter 1.26**). While eclogite, the high-velocity/high-density/high-pressure equivalent of oceanic basalt, is observed in subducting oceanic crust below about 100 km depth, it is seen only rarely in the continental lithosphere where it is generally interpreted to be evidence of a relict slab (e.g., Bostock, 1997). In general, high-velocity bodies consistent with large volumes of eclogite are not observed in the continental mantle (e.g., Gao et al., 2002; James et al., 2001; Schimmel et al., 2003; VanDecar et al., 1995).

Seismic velocities in the continental lithospheric mantle most commonly correlate with the age of last tectonomagmatic activity in the area rather than the age of the overlying crust. A prime example is North America, where a sharp lithospheric boundary, approximately along the Rocky Mountain Front, is observed between the stable platform of eastern North America and the tectonically active western United States, much of which is underlain by Precambrian basement. The contrast in upper mantle V_s between stable North America and tectonic western North America, while highly variable, is as much as 10% or even more in places. Although both temperature and composition affect seismic velocities of rocks in the mantle, temperature exerts the dominant control (Goes and van der Lee, 2002; James et al., 2004; Lee, 2003). Nonetheless, Godey et al. noted that a 2% increase in velocity can be explained either by a 120 °C decrease in temperature, by a 7.5% depletion in iron, or by a 15% depletion in aluminum (Godey et al., 2004). Assuming that temperature is the only variable, a ~10% difference in V_s velocity between Basin and Range Province lithospheric mantle and cratonic lithospheric mantle implies that the cratonic mantle is some 600 °C colder. Godey et al. estimated that the coldest part of the Canadian Shield is about 800 °C colder than tectonic North America at 100 km depth. Indeed, cratons everywhere are characterized by very low geotherms (Nyblade and Pollack, 1993). In general, heat flow calculations of temperature differences at depth between cratons and tectonic regions are consistent with results where seismic velocities are inverted to obtain thermal structure (Goes and van der Lee, 2002). Given nominal estimates for heat production in Archean crust and mantle and assuming a typical cratonic surface heat flow of 40 mW m^{-2} (Pollack and Chapman, 1977), the calculated temperature at 100 km would be about 800 °C. Adding 600 °C to this would push much of the mantle beneath western United States almost to the dry melting point of peridotite (~1450 °C). If temperature differences of the same magnitude persist to 150 km depth, where the temperature beneath a craton is of order 1050 °C (Nyblade, 1999), then adding 600 °C to this would place the western US mantle well above the dry melting temperature of peridotite (Carlson et al., 2005). While there is active volcanism locally in the western United States, there is no seismic evidence that any parts of the shallow mantle are substantially molten anywhere. Consequently, the large seismic velocity difference between various regions of the continental mantle is unlikely to be solely the result of varying temperature. This constraint provided the basis for Jordan's (1975) tectosphere hypothesis in which he introduced the principal of temperature–depletion compensation (isopycnic hypothesis) to account for differences between cratons and oceans (Jordan, 1975, 1978, 1979, 1981, 1988). Godey et al. (2004) calculated both temperature and compositional differences from a joint inversion of S-wave velocities and density perturbations, concluding that the maximum δT at 100 km depth between craton and tectonic mantle was −440 °C and δFe was −4%. Even a perturbation of 440 °C, however, appears to put the mantle temperature in tectonic regions above the dry melting temperature if it extends to depths much in excess of 150 km. Curiously, the S-wave velocity perturbations calculated by Godey et al. do *not* decrease significantly at depths greater than 100 km, whereas those of van der Lee and Nolet (1997) and others do (Carlson et al., 2005).

The question of whether a significant low-velocity zone (asthenosphere) exists beneath the continental lithosphere remains an unresolved topic of debate. The base of the oceanic lithosphere is marked nearly everywhere by a strong decrease in V_s at depths generally less than 100 km. Low-velocity zones in the uppermost mantle are clearly seen under many tectonically active continental regions (e.g., Karlstrom and Keller, 2005, and articles therein), but most are associated with relatively recent tectonomagmatic activity that has been superimposed on pre-existing Proterozoic or even Archean structures. The absence of mantle roots beneath the Wyoming and North China Cratons appears to be an extreme example of high-temperature Phanerozoic overprinting (see summary by Carlson et al. (2005) and references therein). Beneath stable continental regions, low-velocity zones tend to be weak or absent. With few exceptions (e.g., Rychert et al., 2005), the base of the stable continental lithosphere is not well imaged seismically: the transition over which the relatively high seismic velocities of stable lithosphere merge into the comparatively lower velocities of the convecting mantle appears to be gradual.

1.16.7 EarthScope, USArray, and the Future of Portable Array Seismology

EarthScope is a major program funded through the US NSF to investigate the structure and evolution of North America and the physical processes controlling earthquakes and volcanic eruptions. USArray, the component of EarthScope specifically aimed at imaging the deep structure of the continent beneath the United States, is conceived as a rolling array of 400 broadband stations that over a 12-year period will occupy more than 2000 sites within coterminous United States and Alaska, each for a period of about 18 months. The 2000-station deployment, with an average grid spacing about 70 km, is to be supplemented by more dense active and passive array deployments aimed at key scientific targets (the 'flexible' component of USArray) and anchored by a regular network of permanent broadband stations. The seismic observations from USArray are intended to provide the foundation for integrated geologic, geochemical, and other geophysical studies to produce a coherent, high-resolution, plate-scale image of the continental lithosphere and the underlying mobile mantle. Besides significantly higher-resolution regional images, one of the most

important contributions of USArray will be the uniform coverage with uniform resolution of deep structures across the very different geologic provinces of North America. The uniform seismic images across the continent will greatly enhance our ability to relate surface geology and detailed lithospheric structure to driving forces and thermal processes within the mantle and to link structures inherited from earlier stages of continental evolution and subsequent plate motion to known and potential geologic hazards. The USArray program within the United States is echoed to some extent by comparable programs in Europe (e.g., EUROArray) and reportedly in China, where plans are being implemented for broadband arrays of several hundred portable instruments that can be deployed across the continent to study deep plate-scale structures (F. Niu, personal communication).

1.16.8 Discussion

Passive array seismology is arguably the most powerful tool available to scientists for the study of continental lithosphere and small-scale heterogeneities in the deeper Earth. Over the past two decades, passive array experiments have evolved from deployments comprising a handful of broadband instruments to major imaging efforts involving hundreds of stations. The images of the deep continental lithosphere produced from these experiments have revolutionized our understanding of continental formation and evolution. Tomographic imaging of increasingly high resolution has been notably successful in underscoring the extent to which continental lithosphere has been shaped and reshaped over geologic time by complexly superimposed tectonic and magmatic events. Western North America is an oft-cited example of massive Phanerozoic overprinting of preexisting Archean and Proterozoic terranes. Structures in the mantle beneath southern Africa exhibit clear evidence of Proterozoic disruption and overprinting of thick Archean tectosphere. Ancient relict structures including remnant downgoing plates have apparently been observed in a number of localities, most notably in western Canada. Lithospheric structures beneath provinces of very similar age and geologic character (e.g., Archean cratons) have proven to differ significantly by region as shown, for example, in the differing structures beneath the Kaapvaal, Slave, Tanzanian, and Fennoscandian cratons.

The maturing of passive array seismology into a powerful system for exploring the deep Earth beneath continents should not overshadow the fact that tomographic and direct waveform images are still well below optimum for reliable geologic understanding of deep structure. High-resolution images are certainly attainable with available broadband data and present-day methodologies. As the pool of broadband instrumentation available through PASSCAL, USArray, and other organizations around the world continues to increase, the size of regions that can be imaged and the sharpness of the images produced will continue to improve. In this respect, national-scale deployments will result in considerably sharpened 'uniform' images on a continent-wide scale, an achievement previously unimagined. Despite the extraordinary increase in the number of instruments available for passive array deployments, particularly in the recent years, a primary limitation on 3-D imaging will remain suboptimum seismometer density for years to come. It is for this reason that array deployments for many of the most ambitious broadband experiments are, even today, still configured as linear transects. With current availability of broadband equipment, only linear arrays can achieve sufficient station density (10–20 km) to enable direct unaliased waveform imaging of deep structure. Similarly, high station densities for 3-D direct waveform imaging on regional scales generally require more instruments than are currently available to individual researchers or groups of researchers, although closely targeted studies involving 100 or more closely spaced seismographs are increasingly common. Advances in satellite and cellular communications for telemetry of seismic data in real time will substantially reduce the manpower required to service equipment in the field and significantly enhance data recovery and data quality. These advanced communication systems are currently in use for the USArray deployment and have already proven their value in substantially streamlined experiment operation and maintenance.

1.17.1 Introduction: Regional Geologic/Tectonic Setting of Central Europe

The complex tectonic history of Central Europe (Figure 1) reflects the breakup of a Neoproterozoic supercontinent(s) (Rodinia/Pannotia) (e.g., Dalziel, 1997) to form the continental fragment Baltica and the subsequent growth of continental Europe beginning with the Caledonian orogeny. Caledonian and younger Variscan orogeneses involved accretion of Laurentian and Gondwanan terranes to the rifted margin of Baltica (East European Craton – EEC) during the Paleozoic (e.g., Pharaoh, 1999). From central Poland northward, the region also experienced volcanic activity during the Permian and tectonic inversion during the Alpine orogeny, which in the south continues today. The Trans-European Suture Zone (TESZ) is a term used to refer to the suite of sutures and terranes that formed adjacent to the rifted margin of Baltica (e.g., Berthelsen, 1992a,b, 1998; Pharaoh, 1999; Ziegler, 1990), and these features extend from the British Isles to the Black Sea region (Figure 1). Understanding the structure and evolution of the TESZ region is one of the key tectonic challenges in Europe north of the Alps. The tectonic evolution of this region shares many attributes with the Appalachian/Ouachita orogen (Golonka et al., 2003a; Keller and Hatcher, 1999) and is certainly of global importance to studies in terrane tectonics and continental evolution. The TESZ is far more complex than a single suture but in a broad sense is the boundary between the accreted terranes and Baltica. The TESZ includes the Teisseyre–Tornquist Zone (TTZ), which has several definitions. Here, we will use the term TTZ to refer to a structural zone associated with the southwestern edge of the EEC.

The Bohemian Massif is a large structural block (Figure 1) that is mostly located in the Czech Republic and is a large, complex terrane whose origin can be traced to northern Gondwana (Africa). In southern Poland, several smaller structural blocks such as the Małopolska Massif (MM; Figure 1) are located adjacent to Baltica and were probably transported laterally along it, similar to Cenozoic movement of terranes along the western margin of North America.

The younger Eastern Alps, Carpathian Mountains arc, and Pannonian Basin (the ALCAPA units) form interrelated components of the Mediterranean arc–basin complex (Figure 1). These features are the result of intricate Mesozoic/Cenozoic plate interactions in the Mediterranean region and are strongly related to the spreading history of the northern and central Atlantic. At that time, closure of the Paleotethys by subduction under the Eurasian megaunit was already completed and the Neotethys fully developed. Smaller ocean basins existed in the southeastern ALCAPA (e.g., Le Pichon et al., 1988; Stampfli and Kozur, 2006). The displacement of Africa relative to the European platform led to a complex sequence of rifting, breakup of continental blocks, seafloor spreading, subduction of oceanic and continental lithospheres, and reamalgamation and suturing of microplates. Considering the Eastern Alps and the adjoining Carpathians, Dinarides, and Southern Alps, the opening and closing of the Meliata and Vardar Oceans in the south and the Alpine Tethys in the north strongly influenced the development of these mountain chains. The

Figure 1 Simplified tectonic map of Central Europe. ATA, Armorican Terrane Assemblage; MM, Małopolska Massif; TESZ, Trans-European Suture Zone.

Adriatic microplate started to move more independently from Africa to the northwest (e.g., Handy et al., 2010). The Alpine orogenic phase occurred in Cretaceous and Upper Eocene after subduction of the Meliata Ocean and Alpine Tethys. This process induced far-reaching overthrusting, folding, and stacking of Austroalpine nappes to the north along the passive European continental margin.

The subduction and closure of the remaining ocean in the area of the Carpathian embayment produced considerable Neogene volcanism, which led to the development of the Pannonian Basin and caused finally the Carpathian arc to evolve into its strongly arcuate shape. Back-arc extension was the dominant process that formed the Pannonian Basin that contains up to 8 km of Neogene strata in its subbasins (e.g., Posgay et al., 1995; Royden, 1993). Due to continued indentation of the Adriatic plate in combination with gravitational collapse directed to the unconstrained margin represented by the Pannonian Basin, major blocks of the Eastern Alps extruded laterally to the east (Linzer et al., 2002; Ratschbacher et al., 1991). Current tectonic activity due to the continuing convergence between Africa and Europe has shifted southward to the subduction zones of the Calabrian and Hellenic arcs. However, strong tectonic activity is still evidenced by seismicity that extends to depths of ~200 km in the Vrancea region north of Bucharest in Romania (**Figure 1**). In addition to being a major crustal-scale feature, the TESZ appears to be a deep-seated boundary because tomographic analysis of the shear-wave velocity structure of the mantle under Europe shows that the TESZ separates regions with high S-wave velocities beneath the EEC from low-velocity regions under the younger terranes (Zielhuis and Nolet, 1994). Another indication of the deep-seated nature of the TESZ was obtained from observations of several hundred earthquakes and explosions located in Europe. To explain the observed blockage of energy from regional seismic events by the TESZ region, the structural anomaly between Eastern and Western Europe must reach at least down to a depth of ~200 km (Schweitzer, 1995).

Early deep seismic sounding (DSS) studies in Central Europe also showed a large contrast of the crustal structure between the accreted terranes, the TESZ, and the EEC (e.g., Ansorge et al., 1992; Guggisberg et al., 1991; Guterch et al., 1976, 1984, 1986, 1992, 1994). The exploration of the lithosphere of the Eastern Alps and the surrounding area by WAR/R (wide-angle reflection/refraction) experiments started around the Eschenlohe quarry, in Southern Germany, about 50 years ago (Giese and Prodehl, 1976). The Alpine longitudinal profile (ALP'75) extended along the axis of the Western and Eastern Alps to the Pannonian Basin (e.g., Scarascia and Cassinis, 1997; Yan and Mechie, 1989). TRANSALP is a seismic traverse over the central part of the Eastern Alps from Munich to Venice (e.g., Gebrande et al., 2006 and references therein), combining steep-angle, high-resolution reflection seismic profiling, wide-angle reflection and refraction tomography (Bleibinhaus and

Gebrande, 2006), receiver functions (Kummerow et al., 2004), and teleseismic tomography (Lippitsch et al., 2003), supplemented by gravimetric studies (Ebbing et al., 2006; Zanolla et al., 2006).

Many nonseismic studies have been undertaken in the TESZ region. For example, heat flow measurements indicate a major change in the thermal regime across Central Europe (Čermák and Bodri, 1998). Using over 3200 heat flow measurements, Čermák and Bodri (1998) explained a number of prominent heat flow anomalies (e.g., Pannonian Basin, French Massif Central, and the Alps) as products of the deep-seated lithospheric processes. In the area of Central Europe, the TESZ separates 'cold' lithosphere of the EEC with low heat flow of 30–40 m Wm^{-2} from 'hot' lithosphere with higher heat flow of 40–70 m Wm^{-2} in the Paleozoic terranes and Carpathians, and even higher values (80–110 m Wm^{-2}) are found in the Pannonian Basin and Eastern Alps (Čermák and Bodri, 1998; Čermák et al., 1989; Majorowicz et al., 2003; Vosteen et al., 2003; Zeyen et al., 2002). The characteristic Moho temperature for the EEC has been estimated to be 500 °C (Majorowicz et al., 2003) and 590–620 °C (Čermák et al., 1989). In the TESZ region, the Moho temperature increases to 650–750 °C, and beneath the Carpathians and Pannonian Basin, it even increases to 800–900 °C (Čermák et al., 1989; Dövényi et al., 1983; Majorowicz et al., 2003).

Gravity and magnetic anomalies indicate significant variations in lithospheric structure (e.g., Królikowski and Petecki, 1995; Petecki et al., 2003; Wybraniec et al., 1998). Bouguer anomalies in the area of the EEC are relatively homogeneous (0 ± 20 mGal) and decrease in the area of the EEC margin down to about −40 mGal. The anomaly field becomes more complex in this region with a large high in the Holy Cross Mountains area and lower values to the northwest along the EEC margin. In the Carpathians, Bouguer anomalies reach values of about −80 mGal and increase into the Pannonian Basin (20–30 mGal), where the crust thins (Bielik et al., 2004, 2010).

Magnetic anomalies along the cratonic part of profiles contain many short wavelength variations from −1500 to +1500 nT that correlate well with tectonic features and intrusions in the Precambrian basement. Further to the southwest in the TESZ, the Carpathian Foredeep and Carpathians, magnetic anomalies are subdued (±100 nT), presumably due to the deeply buried magnetic basement. Except in areas of Tertiary volcanism, magnetic anomalies are also subdued in the Pannonian Basin because of the thick cover of sedimentary rocks.

1.17.2 A New Generation of Long-Range Seismic Experiments

From 1997 to 2003, Central Europe was covered by an unprecedented network of seismic refraction experiments to investigate its complex lithospheric structure (Brückl et al., 2003; Grad et al., 2003b; Guterch et al., 1999, 2003a,b). These experiments (POLONAISE'97, CELEBRATION 2000, ALP 2002, and SUDETES 2003) were only possible due to a massive international cooperative effort. Acronyms of these experiments are: POLONAISE'97 – Polish Lithospheric Onsets – An International Seismic Experiment, 1997; CELEBRATION 2000 – Central European Lithospheric Experiment Based on Refraction, 2000; ALP 2002 – Eastern Alps and adjacent regions, 2002; SUDETES 2003 – Sudetes Mountains and adjacent regions, 2003. The total length of all the profiles recorded is ~20 000 km, and during these four experiments, a total of 295 large explosions provided the seismic sources. The number of seismic stations used in these experiments ranged from 640 in the POLONAISE'97 to 1230 in CELEBRATION 2000. Distances between shot points were usually ~50 km. As a result of these experiments, a network of seismic refraction profiles (**Figure 2**) now extends from the EEC (east of the Baltic Sea), along and across the TESZ region of Poland and the Bohemian Massif, through the Carpathians, Sudetes, and Eastern Alps, to the Pannonian Basin, the Dinarides, and the Adriatic Sea (Brückl et al., 2003; Grad et al., 2003b; Guterch et al., 1998, 1999, 2001, 2003a,b, 2004). The high-quality seismic data obtained reveal a variety of both the P- and S-wave phases. The main results were published in Guterch et al. (1999, 2004, 2007), Grad et al. (1999, 2002a,b, 2003a, 2005, 2006, 2007, 2008, 2009), Jensen et al. (1999, 2002), Środa and POLONAISE P3 Working Group (1999), Wilde-Piórko et al. (1999), Krysiński et al. (2000, 2009), Bayer et al. (2002), Czuba et al. (2002), Janik et al. (2002, 2005, 2009, 2011), Środa et al. (2002, 2006), Winchester et al. (2002), Růžek et al. (2003), Hrubcová et al. (2005, 2008, 2010), Majdański et al. (2005, 2007), Malinowski et al. (2005, 2009a,b), Brückl et al. (2007, 2010), Šumanovac et al. (2009), and Narkiewicz et al. (2011).

These experiments also relate to the German KTB project, the BOHEMA, ALPASS, and PASSEQ 2006–2008 seismic tomography experiments and numerous Czech–German projects on the geodynamics of the West Bohemia/Vogtland seismically active region. The teleseismic experiments provided exciting new insights into the structure and evolution of the lithosphere in this region (Brückl et al., 2010; Plomerová et al., 2003; Wilde-Piórko et al., 1999, 2008).

The principal specific scientific goals of the POLONAISE'97, CELEBRATION 2000, ALP 2002, and SUDETES 2003 experiments were the following:

- Investigate the deep structure of the southwestern margin of the EEC (southern Baltica) and its relationships to younger terranes
- Delineate the major terranes and crustal blocks in the TESZ region (e.g., Upper Silesian block and blocks exposed in the Holy Cross Mountains)
- Investigate the origin and structural framework of the Pannonian Basin and its subbasins
- Investigate the nature and extend of thrust faulting along the northern front of the Carpathians
- Investigate the structure and evolution of the Eastern Alps and their relationships with adjacent features
- Investigate the structural relationships between the structural elements of the Bohemian Massif and adjacent features
- Construct a three-dimensional (3-D) model of the lithospheric structure in the area
- Evaluate the implications of the Earth models derived for natural resources and earthquake hazards
- Evaluate and develop geodynamic models for the tectonic evolution of the region.

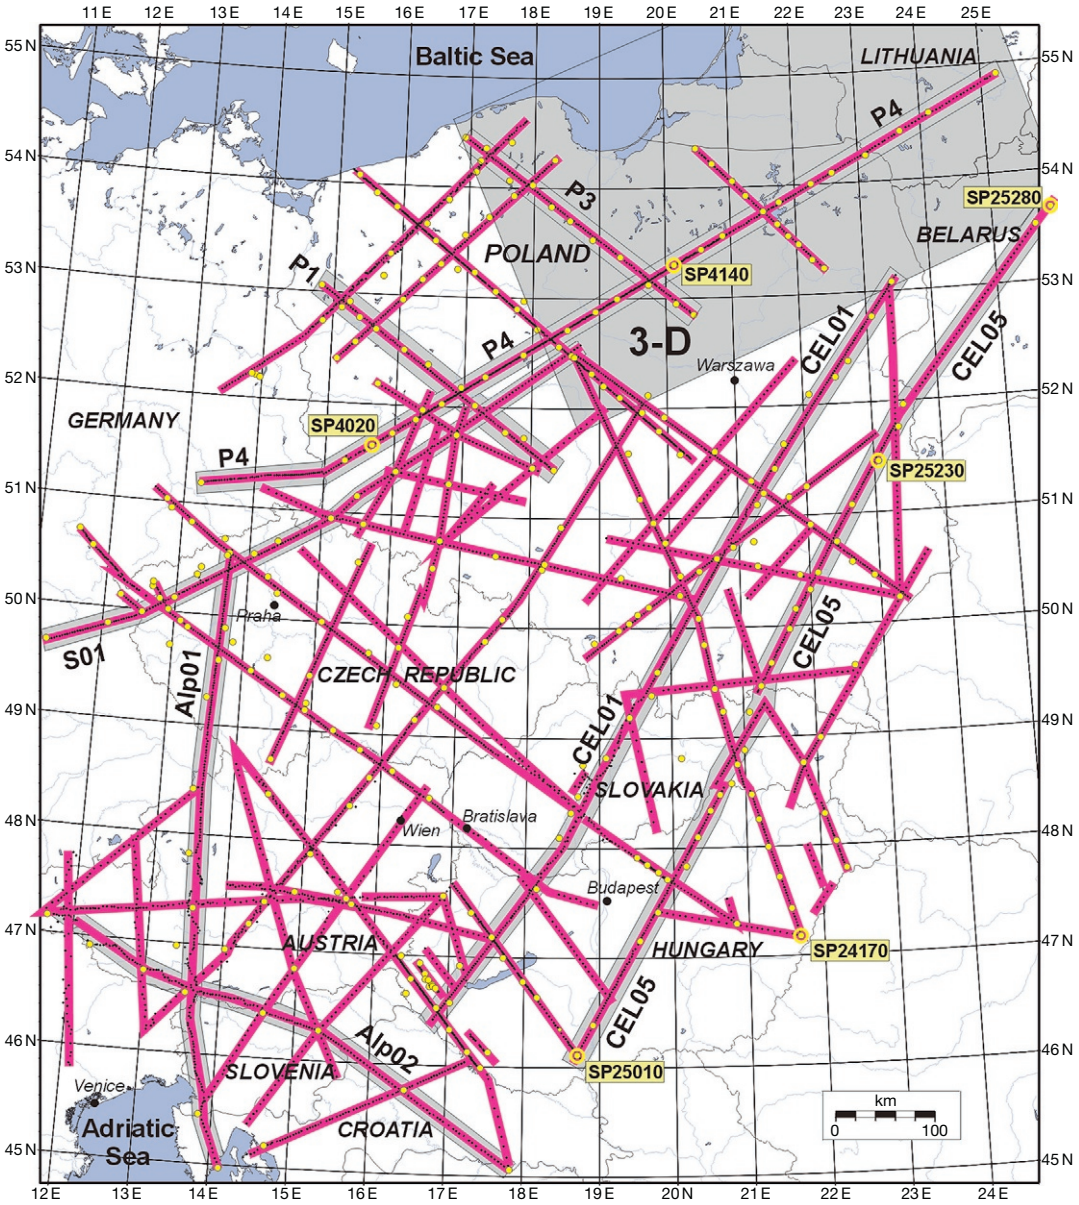

Figure 2 Location of seismic profiles recorded in Central Europe during the POLONAISE'97, CELEBRATION 2000, ALP 2002, and SUDETES 2003 experiments. Pink lines show the seismic profiles whose total length is ~20 000 km, with ~7000 seismic receiver positions (small black dots). Yellow dots show 295 large shot locations. Gray lines show position of POLONAISE'97 profiles P1, P3, and P4, CELEBRATION 2000 profiles CEL01 and CEL05, ALP 2002 profiles Alp01 and Alp02, and SUDETES 2003 profile S01 for which models are shown in **Figures 6–12**. The gray area shows the area of 3-D investigations presented in **Figure 14**. Yellow dots show location of shot points SP25010, SP4020, SP24170, SP25230, SP4140, and SP25280 for which record sections are shown in **Figures 3–5**.

When all the individual results are completed and integrated, these experiments will provide an unprecedented 3-D image of the evolution and assembly of a continent.

1.17.3 Characteristics of the Seismic Wavefields along Profiles for Different Tectonic Provinces (Terranes)

CELEBRATION 2000 profile CEL05 and POLONAISE'97 profile P4 are most representative for the characteristic of seismic wavefields in Central Europe because of their length. The 1420 km long profile CEL05 is the longest recorded in the CELEBRATION experiment (Figure 2). It begins in Hungary; crosses the Slovak Republic, Poland, and Belarus; and ends in Northwestern Russia. The southwestern part of the profile (0–200 km) lies in the Pannonian Basin. The profile then crosses a tectonically complex zone that includes the Carpathians and their foredeep (200–500 km) and then crosses the TESZ (500–700 km), including the MM, Lublin Trough, and TTZ (Figure 1). The northeastern part of the profile (700–1420 km) crosses the EEC (Figures 1 and 2). Data from

26 explosions made along this profile were collected using over 360 modern seismic recorders, with a nominal station spacing 2.8 km in Hungary, Slovakia, and Poland and 4.6 km in Belarus and Russia. More details about the layout of the experiment are provided in Guterch et al. (2001, 2003b).

The P-wavefield on the CEL05 record sections has high signal-to-noise ratio, particularly for the southern (Pannonian Basin) and the northern cratonic parts of the profile. Identification and correlation of seismic phases were done manually on a computer screen using software that allows flexible use of scaling, filtering, and reduction velocity (Środa, 1999; Zelt, 1994). Clear arrivals of refracted and reflected waves from sedimentary layers, the crystalline crust and the upper mantle, were typically observed up to offsets of 200–300 km and for some shots, even over 900 km. Examples of record sections for profiles CEL05, CEL04, and P4 are shown in Figures 3–5.

General observations about the data are that waves from sedimentary cover (P_{sed}) are observed as first arrivals in the vicinity of shot points up to offsets of only 1 km on the EEC, while they are observed to offsets of 10–20 km in the TESZ

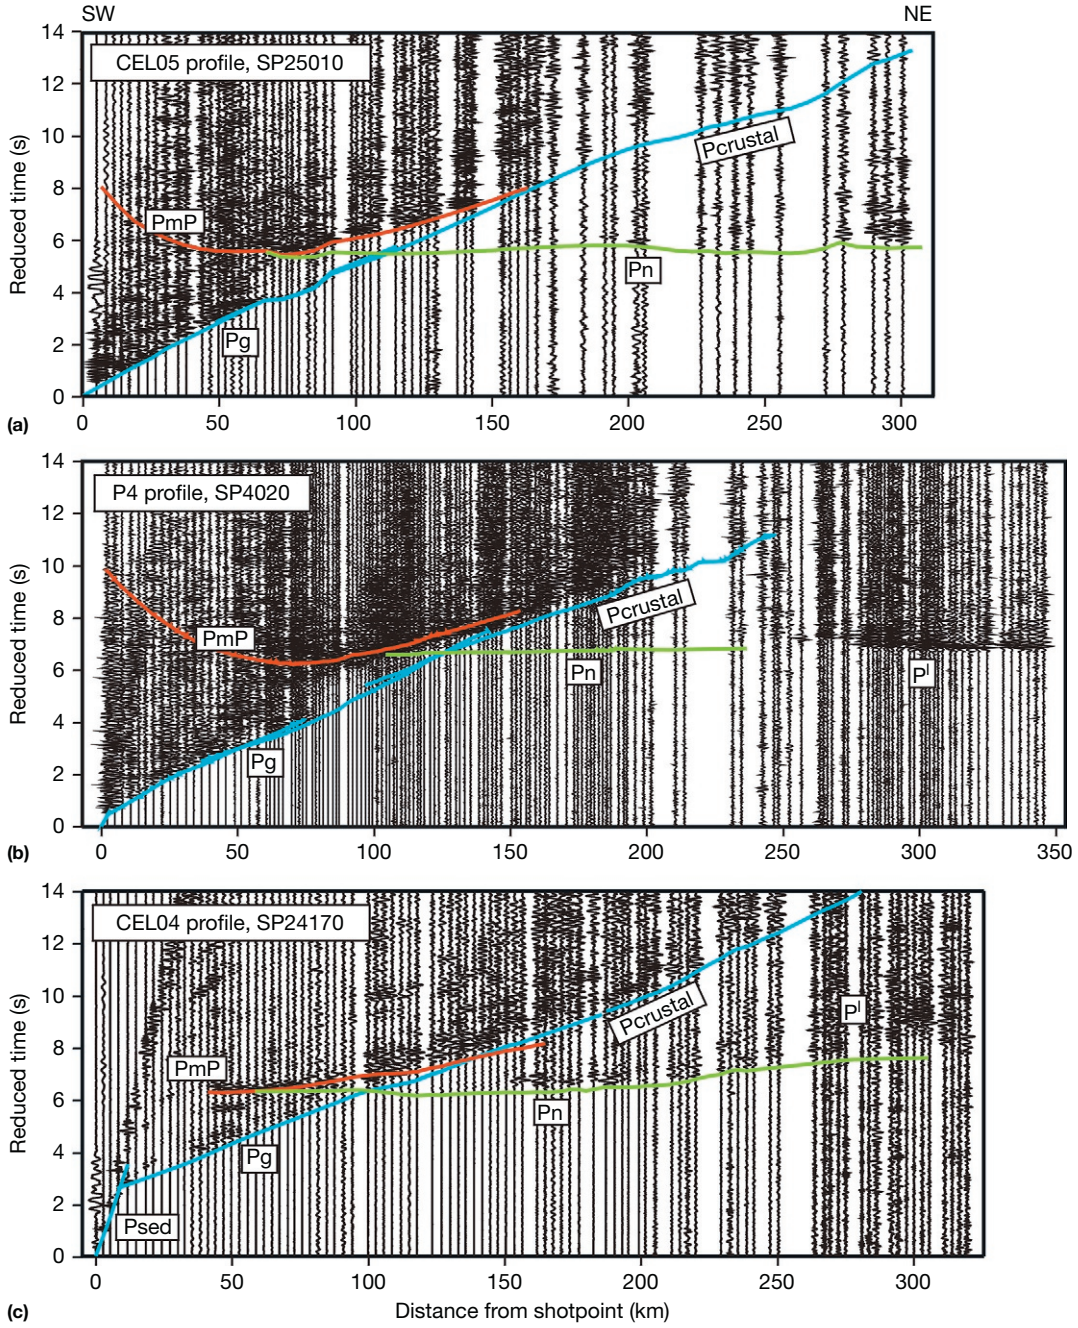

Figure 3 (a–c) Examples of P-wave record sections for seismic profiles in the area of Central Europe (for shot points' location, see Figure 2). P_g, $P_{crustal}$, P_mP, and P_n – crustal and Moho phases. Reduction velocity for all sections = 8 km s^{-1}.

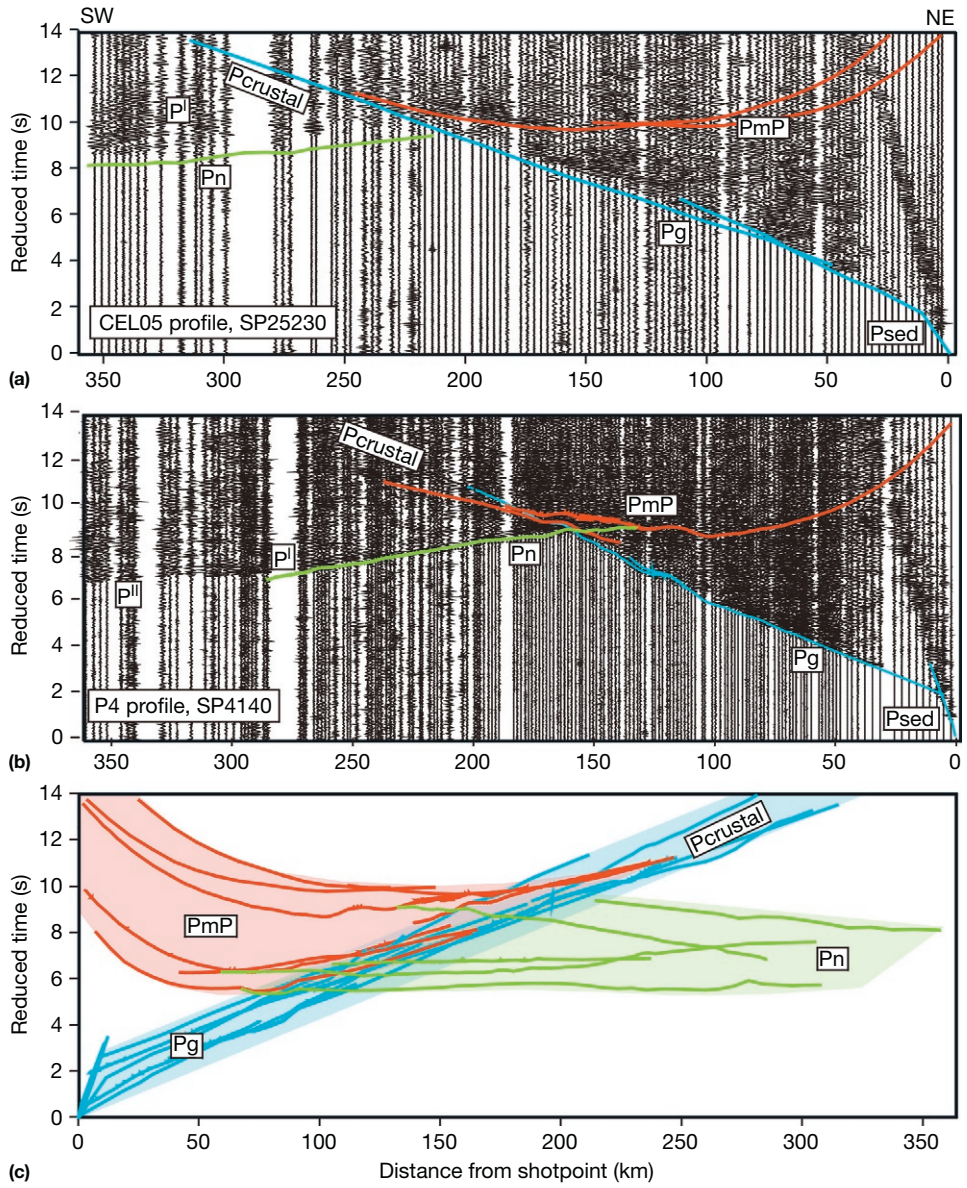

Figure 4 Examples of P-wave record sections ((a, b); for location, see **Figure 2**) and comparison of travel times (c); note the large variation of the arrival times (reaching 3–6 s) of the P_g, $P_{crustal}$, P_mP, and P_n phases, which indicate large differences in the crustal and uppermost mantle structures across the region.

region and even ~30 km in the Carpathians. Their apparent velocities range from 2.5 to 5.5 km s^{-1}. After these arrivals, the P_g phase that travels in the crystalline basement (upper crust) is recorded to highly variable offsets of 1–250 km. The slowest arrivals occur to the southwest toward the Carpathian Foredeep and Carpathians, and at offsets of 100–150 km, they are ~2 s late compared with other directions. As discussed in the succeeding text, the highly variable crustal structure along profile CEL05 results in mantle arrivals also becoming first arrivals at highly variable offsets.

In the Pannonian Basin region, the seismic wavefield is characterized by strong P_g arrivals to offsets of ~50 km. For offsets out to 150 km, the amplitude of the P_g wave is small relative to the dominant reflection from the Moho (P_mP). Reflections from the top of the middle crust (P_c) are well correlated and observed throughout the whole 'Pannonian' part of the profile. Reflections from the top of the lower crust (P_{lc}) are well correlated and observed throughout the whole 'cratonic' part of the profile. Refractions from the middle crust and lower crust are correlated as secondary arrivals in the seismic sections, primarily at long offsets where refractions merge with wide-angle reflections to form the overcritical phases $P_{crustal}$ and $S_{crustal}$, which in some cases are well recorded to offsets of ~300 km. These phases are important for determining the velocities in the middle crust and lower crust, particularly for the Pannonian crust where the velocities of these layers are 6.2–6.6 km s^{-1}. In the 'Pannonian' region, the phase diving in the uppermost mantle (P_n) has relatively low amplitudes and low apparent velocities (7.9–8.0 km s^{-1}). The intercept time for P_n is only ~6 s (for reduction velocity 8 km s^{-1}), and its crossover distance with the crustal (P_g) arrivals is only 100–120 km. These observations clearly show

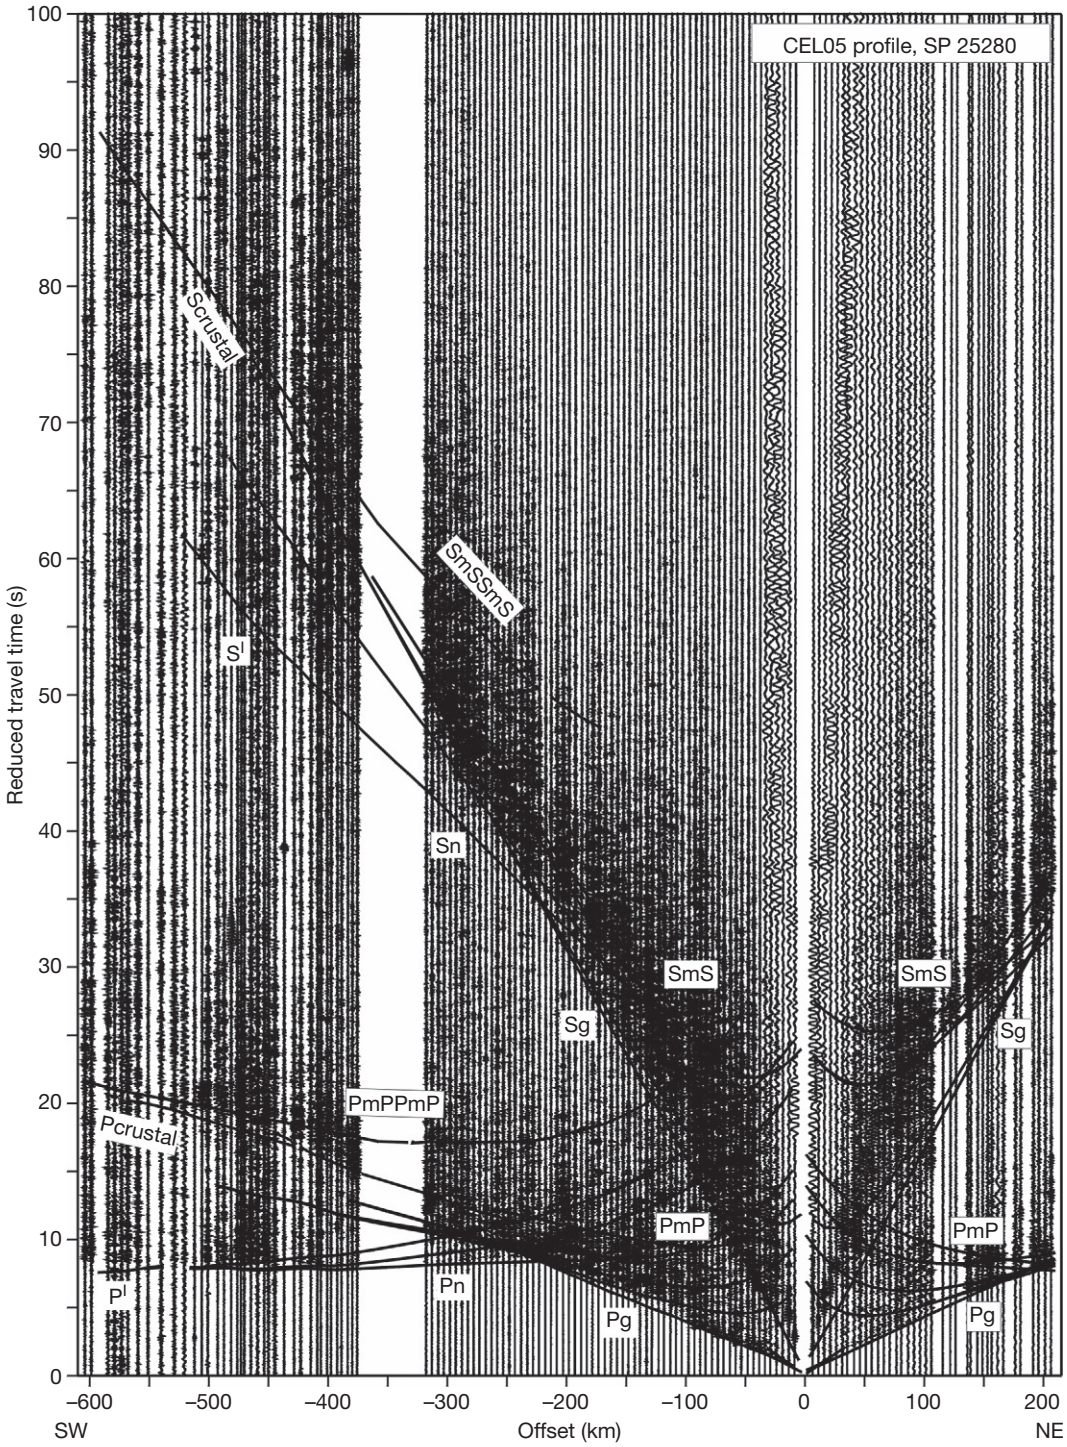

Figure 5 Example of P- and S-wave record section for CELEBRATION 2000 profile CEL05 (Figure 2). Amplitude-normalized seismic record sections for SP25280 showing the full wavefield, including both P- and S-waves with theoretical travel times calculated for the model of the crust derived using the SEIS83 ray-tracing technique. Note the P_mPP_mP and S_mSS_mS waves that are reflected twice from the Moho discontinuity and free surface and high-quality lower lithosphere phases recorded to long offsets. Reduction velocity = 8 km s^{-1}.

that the Moho in the Pannonian Basin is shallow. Starting at offsets of ~200 km, arrivals from the mantle lithosphere (P^I and P^{II}) were observed for some shots.

The wavefield observed in the Carpathian region is complex as is the known geologic structure. First arrivals (P_g) are distinct up to ~100 km offset and are characterized by large variations in apparent velocity and amplitude. Midcrustal reflections (P_c) are usually recorded at short distance intervals (20–50 km) and are also characterized by variations in apparent velocity and amplitude. P_n arrivals were only fragmentarily recorded in the

Carpathians. This characteristic attribute of the wavefield testifies to the complex structure of the crust–upper mantle transition in this region. The observed wavefield is similar in the adjacent Carpathian Foredeep to the northeast. However, waves with low apparent velocities (4.0–5.0 km s^{-1}) are observed up to 30–50 km offsets, and midcrustal phases are even more complex.

In the TESZ area, the character of the wavefield is more uniform, and the travel times of both refracted first arrivals (P_g) and waves from the Moho and uppermost mantle (P_mP and P_n) show clear evidence that the crystalline basement and crust–upper mantle boundary are deep. Compared to the Pannonian area, the P_n wave intercept time is much later (reduced time 8.0–8.5 s for reduction velocity 8 km s^{-1}). The crossover distance between crustal (P_g) and mantle refractions (P_n) is also much larger. Waves generated in this region are well recorded, particularly toward the northeast in the EEC.

The P-wavefield recorded on the EEC is uniform with high signal-to-noise ratios. Due to the thin sedimentary cover, the P_{sed} phase produces first arrivals only to offsets of 1–10 km from the shot point. The P_g phase has a uniform character and is observed in the first arrivals up to ~200 km offsets, with apparent velocities increasing with distance from 6.0–6.2 to 6.6–7.0 km s^{-1}. These crustal waves continue to overcritical distances of up to 250–350 km. Relatively small amplitudes characterize waves from the middle crust, which indicates small contrasts at seismic boundaries and small velocity gradients within layers. Waves reflected from the Moho (P_mP) are the dominant arrivals in the offset interval of 90–120 to 200–250 km. P_n arrivals have small amplitudes, and their apparent velocities are 8.1–8.2 km s^{-1}. The intercept time for P_n occurs at a reduced time of ~8 s, which is ~2 s more than for the Pannonian crust. For a number of shot points, well-recorded waves from the lithospheric mantle were observed up to 400–500 km offsets and even to 800–1200 km. For the northern shot points, an unusual variety of P- and S-wave phases were recorded, and these phases are shown in Figure 5. For shot point SP25280, P- and S-waves were doubly reflected from the Moho, and good-quality lower lithosphere phases P^I and S^I were observed.

Examples of record sections from profile P4 (Figure 2) are presented in Figures 3 and 4. Refracted waves from the sedimentary cover (P_{sed}) are observed as first arrivals in the vicinity of shot points at offsets 1–15 km. The apparent velocity is 4.0–5.5 km s^{-1} in the southwestern part of the profile, decreasing northeastward to 2.5–3.5 km s^{-1}. The sedimentary strata are far thicker in the Polish Basin than in the two surrounding platform areas. Individual, thin sedimentary layers cannot be modeled outside the Polish Basin because of the relatively coarse (1.5–3.0 km) receiver spacing compared to the local thickness of the sedimentary column.

Following the arrivals from the sedimentary cover (P_{sed} phase), the refraction from the crystalline upper crust (P_g) is detected as first arrivals to offsets of 100–200 km. The basement topography and variations in sedimentary structure can explain the undulation in the arrivals of this phase in most of the seismic sections. There are no abrupt transitions between upper and middle crustal refractions; instead, a gradual transition between P_g and refractions from the layer below is observed. The P_g phase is observed to offsets of 100–150 km along the southwestern end of the profile with apparent velocities of 5.5–6.0 km s^{-1}. To the northeast, this phase is observed to larger offsets and has higher apparent velocities of 6.0–6.25 km s^{-1}. Refractions from the middle crust and lower crust are correlated as secondary arrivals in the seismic sections ($P_{crustal}$ and $S_{crustal}$), primarily at far offsets where the refractions merge with wide-angle reflections. They are recorded up to 200–300 km offset and are very important for the determination of velocities in the middle crust and lower crust.

The crust is highly reflective and several reflections are correlated. Reflections from the top of the middle crust can be correlated on most of the record sections, and reflections from the top of the lower crust (P_c) are observed throughout the profile. Compared with the southwestern end of the profile, this phase is 2 s later in the central part of the profile and 1 s later in the northeastern part. This phase shows varying amplitudes along the profile and is followed by a long coda of lower crustal reflectivity (Jensen et al., 2002).

The crossover distance between crustal and mantle refractions (P_n) varies considerably along the profile, demonstrating that significant variations in crustal thickness and velocity structure are present. In the southwest, this crossover distance is 110–130 km. In the central and northeastern part of the profile, the crossover distance is ~190 km, and at the northeastern end of the profile, it is 205–230 km.

Reflections from the Moho (P_mP) are observed in almost all the seismic sections. The P_mP phase is delayed by 2 s for shots in the central part of the profile and by 1 s for shots in the northeast compared with shots in the southwest. The critical offset, where the amplitudes are largest, is 80–105 km in the southwest, 130–145 km in the central part of the profile, and 150–165 km to the northeast. The postcritical P_mP phase is commonly observed to offsets of 150 km in the southwest and to 220 km (in the some cases, up to 270 km) in the northeast. In general, the precritical P_mP phase is identified from offsets of 60 km in the southwest and 120 km in the northeast. These differences indicate pronounced structural variations along the profile.

The refraction from the upper mantle (P_n) can be identified as a first arrival in most of the seismic sections. The apparent velocity varies between 8.0 and 8.5 km s^{-1} along the profile, although a much higher apparent velocity (up to more than 9 km s^{-1}) in the central part of the profile indicates an abrupt change in Moho depth. Reflections from the upper mantle are observable in some of the seismic sections and were discussed in a regional sense by Grad et al. (2002a, 2003a).

1.17.4 Examples of 2-D and 3-D Modeling of the Earth's Crust and Lower Lithosphere

Analysis of the seismic wavefields began with tomographic inversion of travel times of refracted (diving) waves observed as first arrivals. This produced very smooth models of the velocity variations in the crust and uppermost mantle. Then, detailed velocity models were derived by ray tracing and synthetic seismogram modeling. The calculations of travel times, ray paths, and synthetic seismograms were made using the ray theory package SEIS83 (Červený and Pšenčík, 1983), enhanced by employing the interactive graphic interfaces

MODEL (Komminaho, 1997) and ZPLOT (Zelt, 1994) with modifications by Środa (1999). The initial velocity model based on the tomographic inversion results was successively altered by trial and error, and travel times were recalculated many times until agreement was obtained between observed and model-derived travel times (within a misfit of the order of 0.1–0.2 s). In the modeling, first arrivals, postcritical waves, reflections, and even multiple reflections were employed.

In addition to matching travel times, synthetic seismograms were calculated to control velocity gradients within the layers and the velocity contrast at the seismic boundaries. The final synthetic seismograms usually show good qualitative agreement with the relative amplitudes of observed refracted and reflected waves.

1.17.4.1 POLONAISE'97 Crustal and Lithospheric Models (Profiles P4, P1, and P3)

In the model of profile P4 derived using forward ray-tracing technique with the SEIS83 program (Figure 6), a large thickness of relatively low-velocity material was also found in the Polish Basin (Grad et al., 2003a). In this basin, velocities of 4.7–5.8 km s^{-1} extend to 18–20 km depth and are underlain by 'basement' with a velocity of ~6.4 km s^{-1}. The model shows variable structure and depth of the basement on both sides of the Polish Basin. The top of the crystalline basement (Precambrian) of the EEC varies from ~8 km in the area adjacent to the Polish Basin at the platform's margin to only ~1 km at the NE end of the profile. The general crystalline basement velocity (6.1–6.2 km s^{-1}) is typical for cratonal areas, but at distances of 610–660 km along the profile, high-velocity (~6.4 km s^{-1}) basement was found. This increase of velocities is very visible and documented on reversed travel time branches of the P_g phase. In the velocity model (Figure 6), the corresponding high-velocity intrusion reaches a depth of ~8 km and could be correlated with the Mazury complex (Mz) and Suwałki anorthosite intrusion (Su), which also correlate with a small positive gravity anomaly. The basement of the Paleozoic platform southwest of the Polish Basin is characterized by velocities of only ~5.8 km s^{-1} and lies at depths of 1–3 km. However, distances of 70–140 km along the model a deeper (1–4 km) boundary where the velocity increases to ~6.15 km s^{-1} is observed. This boundary rises to its minimum depth at distance ~125 km, which corresponds to the Wolsztyn Ridge that is characterized by a positive gravity anomaly. Velocities of 6.2–6.4 km s^{-1} are interpreted to extend to depths of ~26 km. The main evidence for this interpretation is overcritical deep crustal reflections observed up to offsets of 200–250 km with velocities <6.5 km s^{-1}. This observation provides evidence for relatively low velocities in the middle crust and lower crust along the SW end of the profile.

A lowermost crust with velocities ≥7.0 km s^{-1} is interpreted to be present from a distance of ~100 km along the model (Figure 6). This interpretation is documented where overcritical crustal reflections at distance 100–220 km along the profile (offset larger than ~200 km) have significantly higher velocities than the P_g wave closer to the shot point (offset 50–150 km).

In the velocity model of profile P4 (Figure 6), the total thickness of the crust changes from ~30 km beneath the Paleozoic platform (0–200 km) to 35–38 km beneath the Polish Basin (200–300 km) and to 42–50 km beneath the EEC (300–800 km). The primary constraints on the Moho topography are the P_mP and P_n phases, and the most complex Moho topography is observed in the contact zone between the Paleozoic platform and the EEC.

There are also some clear phases that are reflections from mantle discontinuities (Grad et al., 2002a), and phases P^I and P^{II} from discontinuities in the uppermost mantle were

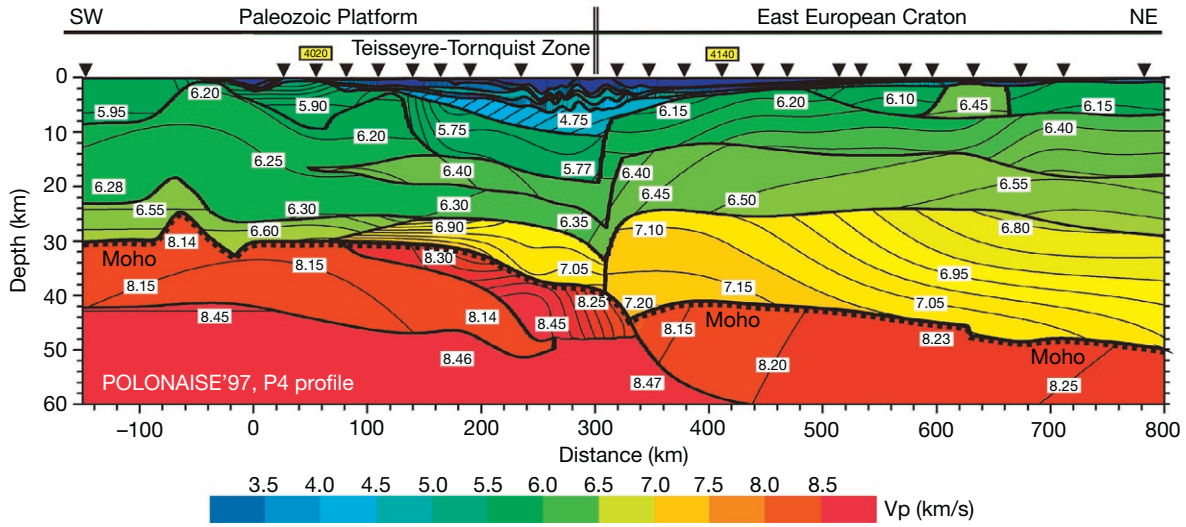

Figure 6 The two-dimensional P-wave velocity model for POLONAISE'97 profile P4 derived by forward ray-tracing modeling using the SEIS83 package (Červený and Pšenčík, 1983). The profile P4 extends across the TESZ almost perpendicularly to the edge of the EEC. The thick solid lines are layer boundaries and the thin lines are isovelocity contours (in km s^{-1}). Triangles show shot points along the profile. Note the thin Paleozoic platform crust (~30 km), thick crust of the EEC (*c.* 45–50 km), and thick sedimentary basin in the TTZ with P-wave velocities lower than 6 km s^{-1} down to ~20 km depth. Vertical exaggeration for the model is ~4.7. Modified from Grad M, Jensen SL, Keller GR, et al. (2003a). Crustal structure of the Trans-European suture zone region along POLONAISE'97 seismic profile P4. *Journal of Geophysical Research* 108: 2541, http://dx.doi.org/10.1029/2003JB002426.

modeled to produce the model in Figure 6. The geometry at the SW end of the model is the result of the top of the dipping body with a velocity of 8.15 km s^{-1}, giving rise to the P^{I} phase from its top and the P^{II} phase from its bottom. The high-amplitude P^{I} and P^{II} phases observed in the record sections and the high apparent velocities of the P_n phase are the basis for this interpretation. The bottom of this layer corresponds in depth with a mantle reflector on profile P1 (Jensen et al., 1999). High velocities (8.3–8.4 km s^{-1}) in the uppermost mantle lithosphere were only found beneath the Polish Basin area. Similar velocities were also found in this area beneath the TTZ (Grad et al., 1999) and P1 (Jensen et al., 1999) profiles. The details of the mantle structure in Figure 6 are nonunique, but high velocities clearly appear to have a tectonic association with the TESZ. The 8.15 km s^{-1} body may represent a continuation of the Variscan lower lithosphere from the southwest. Velocity in the uppermost mantle beneath the EEC increases systematically to the northeast from ~8.15 km s^{-1} at a distance of 350 km on the model to 8.25 km s^{-1} at the northeast end of the model.

A detailed model of seismic velocity variation along POLONAISE'97 profile P1 in northwestern Poland is presented in Figure 7(a). Despite its location behind the Variscan

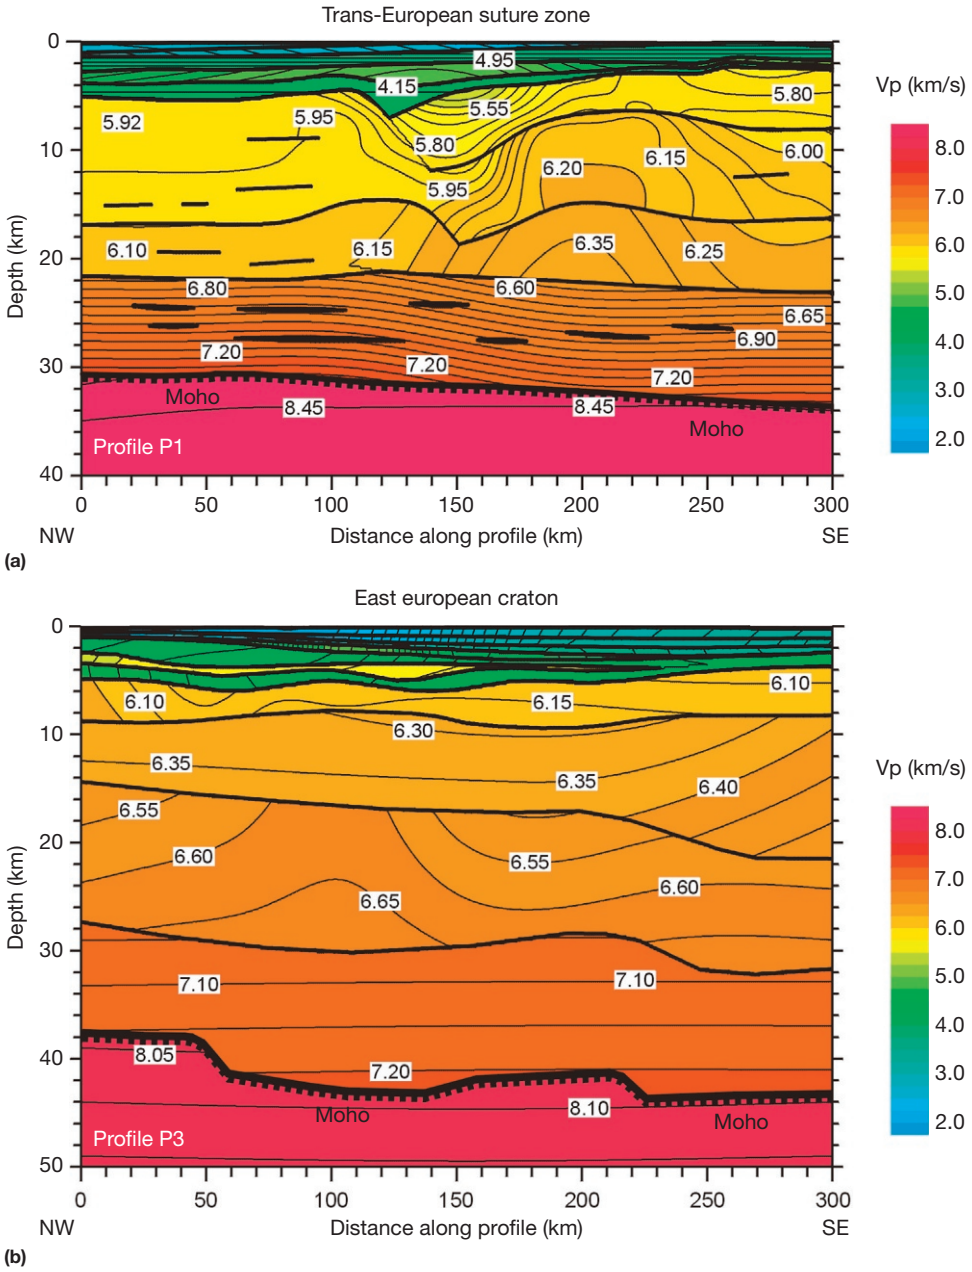

Figure 7 Two-dimensional P-wave velocity model for POLONAISE'97 profile P1 (a) and profile P3 (b) derived by forward ray-tracing modeling using the SEIS83 package (Červený and Pšenčík, 1983). The profiles are located in Figure 2. The thick solid lines are layer boundaries and the thin lines isovelocity contours (in km s^{-1}). Vertical exaggeration for both models is ~4.2. Compiled from Jensen et al. (1999) and Środa and POLONAISE P3 Working Group (1999).

deformation front, the model indicates that the crust below the profile has a Caledonian origin or, alternatively, originates from Baltica and that Variscan deformation was thin skinned in this area. The seismic model shows several new findings from the study area (Jensen et al., 1999).

- Sediment thickness decreases southwestward from 6 to 3 km. There is an indication for tectonic activity during deposition of the Paleozoic sequence.
- The seismic velocities are very low (6.1–6.2 km s^{-1}), down to 20 km depth, indicative of rocks of sedimentary or volcanic origin.
- The lower crust is characterized by a high velocity (6.7–7.5 km s^{-1}), a high vertical velocity gradient, and strong, ringing reflectivity.
- The crust is 30–33 km thick along the profile with a gradual southeastward thickening.
- The P_n velocity of the sub-Moho mantle is high (>8.2 km s^{-1}).

The area south of the Caledonian deformation front (CDF) in Northern Germany and southern Denmark shows similar characteristic features, indicating that the crust between the southeastern North Sea and Poland originates from the same microcontinent (East Avalonia), which was amalgamated to Baltica during the Caledonian orogeny.

A detailed model of seismic velocity variation along POLONAISE'97 profile P3 in the EEC, parallel to the TTZ, is presented in **Figure 7(b)**. The crustal model developed by 2-D ray-tracing forward modeling is characterized by a subhorizontal uniform structure, although the boundaries of several basement provinces are crossed (Środa and POLONAISE P3 Working Group, 1999).

- The sedimentary cover consists of seven layers with a total thickness of 4–6 km. The P-wave velocities range from 2 to 5.7 km s^{-1}.
- The crystalline crust consists of three parts: the upper, middle, and lower crust with P-wave velocities of 6.1–6.4 km s^{-1}, 6.55–6.7 km s^{-1}, and 7.05–7.15 km s^{-1}, respectively.
- The total crustal thickness is 38–44 km and the P_n velocity is 8.05–8.1 km s^{-1}.
- Following the P_n wave, another phase P^I with an apparent velocity of about 8.3 km s^{-1} was interpreted as a weak reflection from a weak discontinuity in the uppermost mantle.
- The V_P/V_S ratio determined for the upper/middle and lower crust was 1.67 and 1.77, respectively. For the sedimentary succession, an average value of 1.80 was assumed. The V_P/V_S ratio for the upper mantle has not been calculated owing to lack of S_n arrivals.

The depth to the Moho along profile P3 ranges from 38 km at the NW end of the profile to 44 km at the SE end. Local changes of depth of the otherwise horizontal Moho, resulting in crustal thickening to the SE, may be associated with tectonic segmentation of the crust, because the depth change occurs close to tectonic unit boundaries. The thickening of the crust in the SE direction is consistent with the trend observed in the EUROBRIDGE profile (EUROBRIDGE Seismic Working Group, 1999). In the upper mantle, a P-wave velocity of 8.05–8.1 km s^{-1} was observed, which is less than that previously found in neighboring areas of the EEC.

POLONAISE'97 produced high-quality data extending to long offsets that resolve velocity discontinuities in the lithospheric mantle. A simplified sketch of the derived 2-D velocity model along the P4 profile is shown in **Figure 8** (Grad et al., 2002a; Wilde-Piórko et al., 2010). In all POLONAISE'97 profiles, the P^I phase indicates a shallow mantle reflector at depths 8–12 km below the Moho. Phases due to deeper features are observed only beneath the longest profile, P4. We found reflectors at depths of about 70, 80, and 90 km in the central part of the TESZ region (180–420 km along profile P4). Complex high and low velocities in the lower lithosphere have been interpreted from other seismic experiments close to the TESZ region as well as within the East European Craton and the Baltic

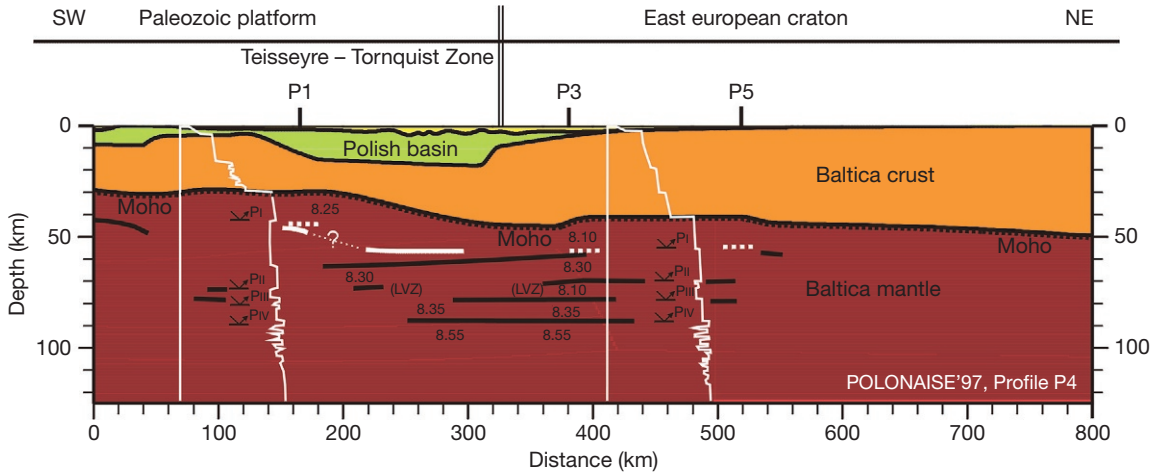

Figure 8 Simplified sketch of lithospheric structure along POLONAISE'97 profile P4 developed by forward ray tracing. Reflectors within the lithospheric mantle beneath profile P4 (thick black lines), the parallel profile P2 (thick white lines), and crossing profiles P1, P3, and P5 (dotted white lines) are marked. Vertical exaggeration for the model is ~1.9. Modified from Grad et al. (2002a).

Shield (Ansorge et al., 1992; BABEL Working Group, 1993; Blundell et al., 1992; Grad, 1989, 1992, 1997; Grad et al., 1986, 1991; Guggisberg and Berthelsen, 1987; Perchuć and Thybo, 1996; Stangl, 1990; Thybo et al., 1994).

A sub-Moho discontinuity with a small P-wave velocity contrast (corresponding to the P^I reflection) was previously detected in the EEC beneath the Baltic Sea by Grad et al. (1991). In the area of the Lithuanian–Belarusian border within the EEC, such a mantle discontinuity was found by the EUROBRIDGE Seismic Working Group (1999) at a depth of about ~65–70 km (Moho depth is ~50 km in this area). The BABEL Working Group (1993) also noted the existence of similar reflected phases but did not model them. From the existing seismic data from the Baltic Shield and the East European Platform, a discontinuity that lies ~10 km beneath the Moho appears to be a general feature of the lower lithosphere. The nature of such a reflector is not understood. One may speculate that the reflector is related to tectonic shearing in the mantle lithosphere. It could also represent a change in mantle composition caused by magmatic processes (i.e., depleted mantle situated just below the Moho that has acted as a source for basaltic magma, while deeper layers are relatively undepleted), or it could represent a change in metamorphic grade of the upper-mantle rocks.

Complex high and low velocities in the lower lithosphere near the margin of the EEC have been interpreted based on the long-offset recordings along the EUGENO-S profile 4 (up to 650 km) and Baltic Sea–Black Sea profile (up to 900 km) (Grad et al., 1986, 1991). Perchuć and Thybo (1996) interpreted a long coda, similar to the coda after the deepest lithospheric reflection, as an indication of a zone of low velocity and strong seismic reflectivity below the depth level of ~100 km under the Baltic Shield. A similar reflective zone beneath the global 8^0 discontinuity at around 100 km depth has been identified globally in all long-range seismic profiles (Thybo and Perchuć, 1997). Based on petrologic and thermal arguments, Thybo and Perchuć (1997) suggested that the reflectivity was caused by pockets of partial melt induced by the lowering of the solidus temperature by small amounts of fluids (Thybo and Perchuć, 1997). The depth to the reflective zone correlates with the heat flow in that it is shallower in 'hot' areas than in 'cold' areas, a feature also observed along the FENNOFLORA seismic long-range profile.

Based on the POLONAISE'97 data, our main finding about the lithospheric mantle is that a series of seismic reflectors extend from the Moho to ~90 km, the deepest interpretable level with the current data set. A seismic reflector is present ~10 km below the Moho throughout the EEC and adjacent areas, independent of the actual depth to the Moho. In general, the reflectivity of the uppermost mantle is stronger beneath the Paleozoic platform and TESZ region than the East European Platform. The deepest interpreted seismic reflector and zone with high reflectivity may mark a change in upper-mantle structure from an upper zone characterized by seismic scatterers of small vertical dimension to a lower zone with vertically larger scatterers, possibly caused by inclusions of partial melt.

1.17.4.2 SUDETES 2003 Crustal Model (Profile S01)

The SUDETES 2003 experiment was the fourth of the series of large seismic refraction and wide-angle reflection experiments performed from 1997 to 2003 in Central Europe, and it covers the gap between the areas of POLONAISE'97, CELEBRATION 2000, and ALP 2002 experiments (Figure 2). The experiment covered mainly the northern part of the Bohemian Massif (including the Eger Rift) and some of the neighboring Polish Basin (TESZ) to the northeast and the Western Carpathians to the southeast (Figure 1). Here, we show a model of the crustal structure beneath profile S01 (Figures 2 and 9). This key profile of the experiment extended southwestward from the margin of the EEC, across the TESZ and Sudetes, and across the Bohemian Massif that contains the active Eger (Ohře) Rift, which is an element of the European Cenozoic Rift System. Good quality seismic data were interpreted using 2-D ray-tracing techniques.

The seismic model shows large variations in the internal structure of the crust (Figure 9), while the Moho topography varies in the relatively narrow depth interval of 28–35 km. Within the Bohemian Massif, a thin sedimentary layer covers the basement characterized by velocities in the range of 5.7–5.8 km s^{-1}. The suspected crystalline basement below the Sudetes Mountains and Fore-Sudetic Monocline (distance 250–450 km along the profile) is characterized by a V_P of ~5.9 km s^{-1}, while below the Polish Basin, V_P is slightly higher, 5.9–6.2 km s^{-1}. The basement velocities observed in the Variscan belt are low compared with those observed for the crystalline basement of the Precambrian EEC (V_P ~ 6.1–6.2 km s^{-1} at depth about 1–5 km). In the area of the Eger Rift, high-velocity bodies (V_P ~ 6.5 km s^{-1}) were recognized. The velocity in the uppermost mantle is about 7.8 km s^{-1} beneath the Saxothuringian and Moldanubian zones and about 7.9 km s^{-1} in the central part of the S01 profile. In the northeastern part of S01 (~400 km to the end of profile), velocities below the Moho are relatively high, ~8.3 km s^{-1}. Additionally, below the Moho, two reflectors were identified in the upper mantle at depths of about 45 and 65 km (not shown).

Along S01, exceptionally clear S_g and S^mS waves were recorded for the area of the Bohemian Massif, where the S-wavefield resembles the P-wavefield. However, even in this case, the phase correlation for corresponding S-wave travel times was difficult. Therefore, in the modeling of S-waves, we used the geometry previously determined from P-wave modeling and by trial and error modeling, fitted S-wave arrivals by varying V_P/V_S for individual layers.

1.17.4.3 CELEBRATION 2000 Crustal Models CEL05 and CEL01

Tomographic and ray-tracing models derived for the structure along profile CEL05 are shown in Figure 10 (Grad et al., 2006) and reveal large variations in the structure of the crust and lithospheric mantle. Figure 10 includes a vertically exaggerated depiction of the topography traversed by the profile. Along most of its length, the profile passes through lowland areas with an average elevation of 200 m. In the Carpathians (200–500 km along profile), elevations range from 400 to 900 m.

In the Pannonian Basin region to the southwest (0–350 km), the crustal structure is relatively simple. However, in the distance interval of ~240–280 km along the profile, a shallow high-velocity body was delineated (V_P ~ 6.4 km s^{-1}). Beneath the upper sedimentary layer and a layer with velocities of ~5.8 km s^{-1}, two almost homogeneous (very small velocity gradient) crustal layers are observed. The velocity increases

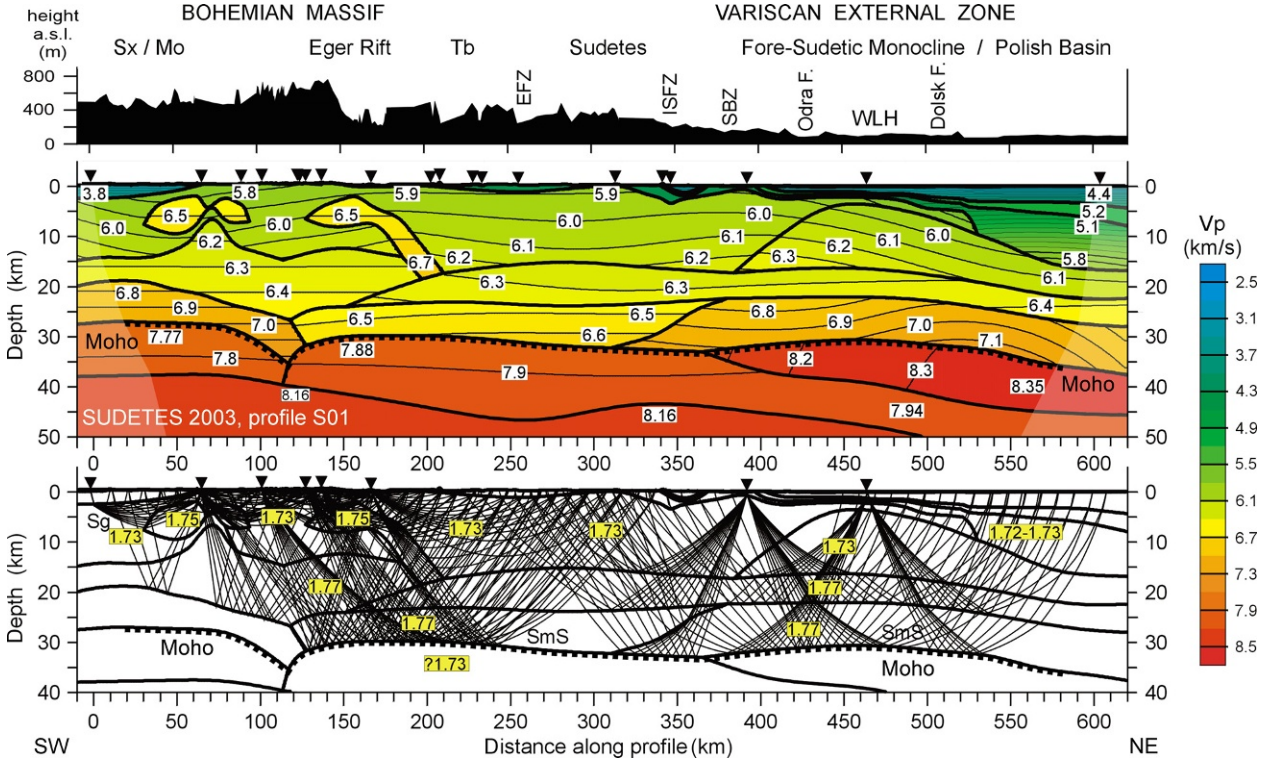

Figure 9 (Top) Topography along the S01 profile. (Middle) Two-dimensional P-wave velocity model for SUDETES 2003 profile S01 derived by forward ray-tracing modeling using the SEIS83 package (Červený and Pšenčík, 1983). For position of the profile, see **Figure 2**. The thick solid lines are layer boundaries and thin lines are isovelocity contours (in km s^{-1}). Triangles refer to shot points. (Bottom) Crustal model with V_P/V_S ratio (in yellow boxes) and with S-wave rays for shot points used in V_P/V_S ratio modeling. Vertical exaggeration is 3:1 for the lithospheric models and ~50:1 for topography. Compiled from Grad et al. (2008).

from ~6.1 to 6.2 km s^{-1} in the depth interval 5–18 km in the first layer and from 6.3 to 6.5–6.6 km s^{-1} to a depth of ~25 km in the second one. The Moho here lies at a depth of only 24–25 km, and the uppermost mantle beneath it is characterized by velocities of 7.95–8.0 km s^{-1}.

Along this profile, the most complicated structure is observed at distances of 350–700 km in the transition from the Pannonian Basin to the EEC. This transition includes the Carpathians and their foredeep, the MM, the rifted margin of the EEC, and the Lublin Trough. This is an area of complex topography, complicated structure in the sedimentary cover (where rocks with velocities <5.5 km s^{-1} reach depths of ~20 km), complex structure within the crystalline crust, and deep Moho (~50 km). In the distance interval 370–400 km, the Pieniny Klippen Belt (PKB), which represents the structural boundary between the Inner and Outer Carpathian units (e.g., Kováč et al., 1993), is represented by a southwest-dipping slab of low-velocity sediments. This slab is a few kilometers thick and can be traced down to ~10 km. The Carpathians are associated with a two-layer crystalline crust with velocities of 5.9–6.2 km s^{-1} and 6.5–6.8 km s^{-1}, respectively; while beneath the TESZ and EEC margin further to the northeast, a three-layer crust is present. In the distance interval 600–670 km along the profile, a dome of relatively high velocities (~6.4 km s^{-1}) protrudes into the upper crust and may represent an intrusion. In the same area, an uplift of the lower crust is also observed. The maximum crustal thickness along the profile (52 km) is observed in the area of the crossing point with profile CEL03 (at distance 600–650 km), where a similar velocity distribution in the crust was also found (Janik et al., 2005).

The EEC occupies the northeast portion of the profile (700–1420 km), and the cratonic crustal structure is similar (thin sedimentary cover and three distinct layers) to that found in other portions of western Baltica (EUROBRIDGE Seismic Working Group, 1999; EUROBRIDGE'95 Seismic Working Group, 2001; Grad and Luosto, 1987, 1994; Grad and Tripolsky, 1995). The crustal thickness varies from 42 to 48 km along this ~700 km long cratonic part of the profile, and velocities in the uppermost mantle vary only slightly: ~8.20 km s^{-1} in the southwest and slightly higher to the northeast. The small change in upper-mantle velocity occurs at ~1050 km along the profile and correlates with small but consistent changes in crustal structure (Grad et al., 2006).

Along the profile, many shot points produced clear arrivals that were reflected in the lower lithospheric mantle (P^I and P^{II} phases), and these phases were modeled by Grad et al. (2006) as shown in **Figure 10**. In the Pannonian–Carpathian area, the P^I wave was usually much stronger than the P_n wave in the same distance range. The corresponding reflector in the mantle lithosphere is subparallel to the Moho but is ~15 km deeper. Thus, it dips northward from the Pannonian Basin under the Carpathians (**Figure 10**). A strong south-dipping reflector was found under the TESZ at a depth of 60–70 km and implies that there is a large velocity contrast between the Pannonian and

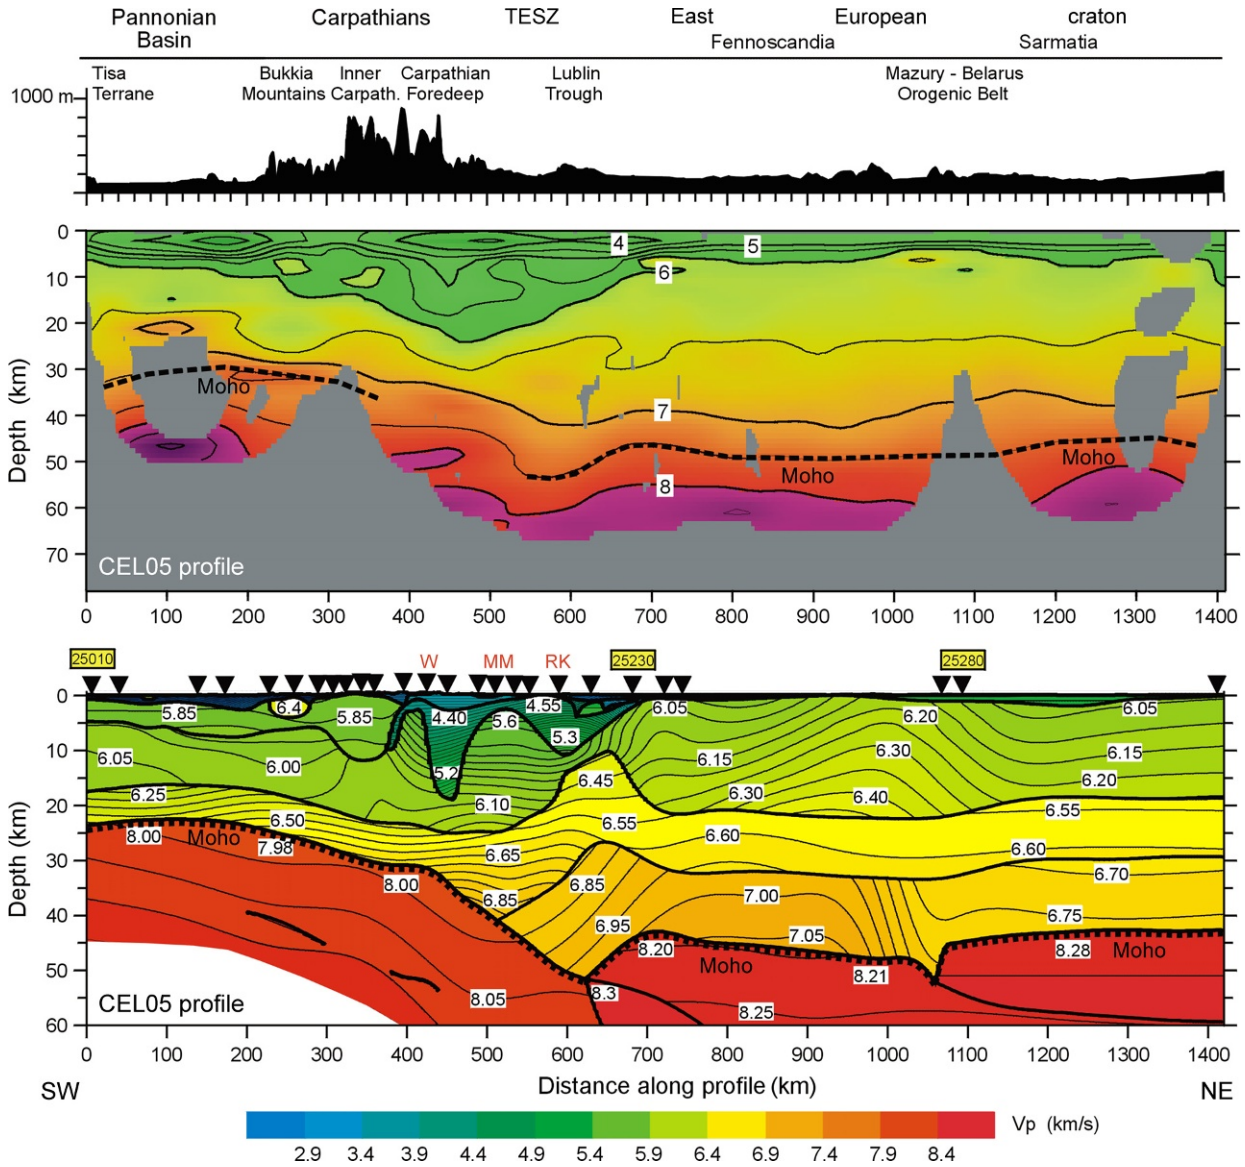

Figure 10 Two-dimensional P-wave velocity model for CELEBRATION 2000 profile CEL05 derived by tomographic inversion (Zelt and Smith, 1992) and forward ray-tracing modeling using the SEIS83 package (Červený and Pšenčík, 1983). The thick solid lines are layer boundaries and thin lines are isovelocity contours in km s^{-1}; triangles refer to shot points. In the upper part, topography along profile is shown. Note the very thin Pannonian crust (~25 km), thick crust of the EEC (~45–50 km), and the thickest crust in the investigated area in the TESZ (~52 km depth at distance 620 km). In the Carpathians and TESZ, sedimentary basins with P-wave velocities lower than 6 km s^{-1} down to 10–20 km depth were found. MM, Małopolska Massif (at 450–550 km of profile); RK, Radom–Kraśnik uplift (at 580–600 km of profile); W, Wysowa (at ~420 km of profile). Vertical exaggeration for ray tracing model is ~6.8. Modified from Grad M, Guterch A, Keller GR, et al. (2006) Lithospheric structure beneath trans-Carpathian transect from Precambrian platform to Pannonian basin: CELEBRATION 2000 seismic profile CEL05. *Journal of Geophysical Research* 111: B03301, http://dx.doi.org/10.1029/2005JB003647.

Baltica mantles. In the EEC area, several reflectors were delineated in the lithospheric mantle.

The tomographic inversion and forward modeling results along profile CEL01 are presented in Figure 11 (Środa et al., 2006). Along CEL01, the EEC is covered by a thin (~2 km) undeformed layer of sediments, except in the Lublin Trough, where sedimentary rocks with $V_P = 4.0–5.5$ km s^{-1} reach a thickness of approximately 10 km. As in nearby areas, the crystalline crust of the EEC consists of three horizontally homogeneous layers, with total thickness of 43–45 km. The EEC upper mantle is characterized by V_P of ~8.05 km s^{-1}. Beneath the Lublin Trough, unusually high velocities of 7.1 km s^{-1} are observed in the upper crust and middle crust, starting at a depth of ~16 km. This anomaly seems to be a continuation of a high-velocity/high-density intrusion located further southwest, which was detected by previous seismic studies in this region (Guterch et al., 1986; Malinowski et al., 2005).

Beyond the EEC margin, beneath the MM and the Łysogóry unit, the dominant feature of the crust is a 20 km troughlike feature (Figure 11). This feature is filled with material whose

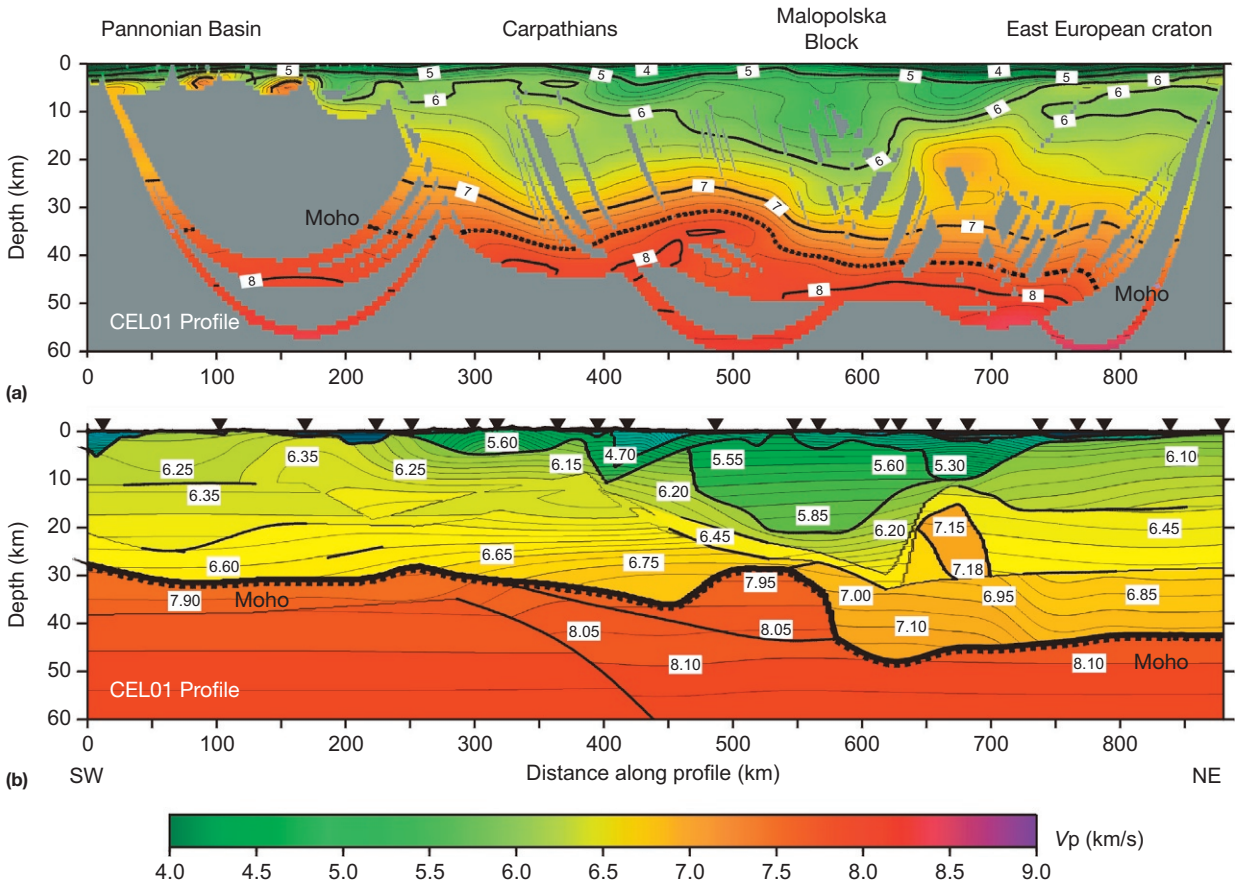

Figure 11 Two-dimensional P-wave velocity models for CELEBRATION 2000 profile CEL01 derived by (a) tomographic inversion (Hole, 1992) and (b) forward ray-tracing modeling using the SEIS83 package (Červený and Pšenčík, 1983). The profile extends from the EEC, across the Trans-European Suture Zone and Carpathians, to the Pannonian Basin. The thick solid lines are layer boundaries and thin lines are isovelocity contours in km s^{-1}; triangles refer to shot points. Note the thin Pannonian crust (~25 km) and the thick crust of the EEC (~45 km). In the Carpathians and TESZ, sedimentary basins with P-wave velocities lower than 6 km s^{-1} extending down to 10–20 km depth were delineated. Vertical exaggeration for both models is ~3.7. Modified from Środa P, Czuba W, Grad M, et al. (2006) Crustal and upper mantle structure of the Western Carpathians from CELEBRATION 2000 profiles CEL01 and CEL04: Seismic models and geological implications. *Geophysical Journal International* 167(2): 737–760, http://dx.doi.org/10.1111/j.1365-246X.2006.03104.x.

velocity is relatively low (V_P = 5.5–5.9 km s^{-1}) and a relatively high vertical gradient of V_P. In the area of the Holy Cross Mountains, Paleozoic rocks with V_P = 5.0–5.3 km s^{-1} are exposed at the surface and have been the target of many geologic studies. Beneath this region, substantial variations of the crustal thickness and the lower crust occur. The crustal thickness of ~44 km does not change from the EEC to approximately the location of the Holy Cross fault, where it rapidly thins to ~32 km to the southwest (Figure 11).

Further to the southwest, a highly asymmetric depression filled by two low-velocity units (V_P = 4.5 and 5.6 km s^{-1}) forms the upper crust in the area of the Outer Carpathians and the Carpathian Foredeep. This low-velocity material forms a south-dipping layer that is approximately bounded on the south by the PKB, where it reaches its maximum thickness of ~10 km. In the ALCAPA (Eastern Alps–Carpathians–Pannonian) unit, the uppermost crust (sedimentary rocks and volcanics) of the Inner Carpathians is a 3–5 km thick layer with V_P values of 5.3–5.6 km s^{-1}. These strata are underlain by the crystalline basement that is characterized by a V_P of 6.1 km s^{-1}. The information about deeper structures of the Inner Carpathian crust is relatively poor due to low signal-to-noise ratio in this area and scarce reflected phases; therefore, no V_P anomalies are discernible. In the Pannonian Basin area, the Danube and Zala Basins show up as areas of low velocities (~3 km s^{-1}) that extend to depths of 3–5 km (Figure 11). Between them, the uppermost crust with V_P of 6.2–6.3 km overlies a layer with lower velocities (5.8–6.0 km s^{-1}) forming a velocity inversion. The middle crust and lower crust of the Pannonian Basin are characterized by V_P values of 6.3 and 6.55 km s^{-1}, respectively. The Moho discontinuity under the Carpathians was found at depths of 30–39 km, with maximum crustal thickness approximately beneath the PKB. The Moho beneath the Pannonian Basin System is relatively flat with a depth of 27–30 km. The V_P of the upper mantle is lowest in the Pannonian Basin and Inner Carpathians area (7.9 km s^{-1}), while further north, beneath the Outer Carpathians, it is higher (8.05–8.1 km s^{-1}). In the upper mantle beneath the Inner and Outer Carpathians, a north-dipping reflector with high impedance contrast was found. It is based on the interpretation of the

strong P^I reflected phase, observed for several shot points; therefore, it is a well-defined structure. To the south, its depth is 45 km, while in the north, it reaches 70 km. This north-dipping mantle discontinuity may represent a shear zone related to collision between the ALCAPA unit and the European plate and possibly ongoing convergence between these units (Środa et al., 2006).

1.17.4.4 ALP 2002 Crustal Models Alp01 and Alp02

The crustal models Alp01 and Alp02 (Brückl et al., 2007) constitute representative seismic cross sections through the Eastern Alps and the adjoining tectonic units to the north, south, and southeast. The P-wavefield on Alp01 and Alp02 record sections has a high signal-to-noise ratio in the Bohemian Massif and the Pannonian Basin. Clear arrivals of refracted and reflected waves from the crystalline crust and the upper mantle are typically observed up to offsets of 200–250 km and for some shots even to over 350 km. In the Alpine area, data quality is variable, the wavefield is complex, and phase correlations are sometimes not as clear as to the north or southeast. In addition to the typical phase identification and travel time picking of phases on record sections (i.e., first-arrival tomography and interactive modeling by ray tracing) stacking of P_g, P_mP, P_n, S_g, and S_mS phases was also applied to take advantage of the 3-D character of the CELEBRATION 2000 and ALP 2002 experiments and to enhance the signal-to-noise ratio (Behm, 2009; Behm et al., 2007). Seismic models derived by the application of these techniques are included in the tectonic interpretation presented in Section 1.17.5.3. In the following discussion, we concentrate on the crustal models for the Alp01 and Alp02 profiles derived by interactive modeling by ray tracing (Figure 12(a) and 12(b)).

To the north (profile distance 0–230 km), Alp01 crosses the Bohemian Massif (Figure 12(a)), where crystalline rocks are exposed at the surface or lie under a thin sedimentary cover. Basement velocities reach 5.6–5.8 km s^{-1} at less than 1 km depth. High-velocity gradients in the uppermost crust followed by low gradients in the middle crust are a characteristic feature of most of the Bohemian Massif. However, in the middle crust (10–19 km) of the Saxothuringian unit (distance interval ~20–80 km), a body with relatively high velocity was delineated (V_P ~6.5–6.6 km s^{-1}). In the Molasse basin, low-velocity (2.5–4.5 km s^{-1}) sediments extend down to about 5 km depth. Structural data gained within the scope of hydrocarbon exploration (Brix and Schultz, 1993) constrain the model in this area. Under the Molasse basin, the velocity structure of the crystalline crust is similar to that of the Bohemian Massif in the north and characterized by relatively low velocities of 6.0–6.5 km s^{-1} down to the Moho (30–38 km).

Beneath the Bohemian Massif and the Molasse basin, strong midcrustal reflections from a depth of 20–30 km were modeled by thin (<1 km) high-velocity 'floating reflectors' with a velocity contrast of about 0.4 km s^{-1}. The physical nature of the 'floating reflectors' is not clear because their polarity cannot be detected unequivocally. The Moho was modeled as the base of a laminated transition zone with a thickness of a few kilometers in the lowermost crust. This transition zone was introduced to correctly model the relatively low P_mP amplitudes. A velocity jump from 6.4–6.5 km s^{-1} in the lower crust to about 8.1 km s^{-1} would produce P_mP amplitudes that were too high.

The complex structure of the upper crust between the North Alpine thrust fault (NAT – distance 300 km) and the Penninic Tauern window (distance ~400 km) (Figure 12(a)) is related to the accretion wedge and nappe stack of the East Alpine orogeny. A priori information from geologic cross sections (Bleibinhaus and Gebrande, 2006; Lüschen et al., 2006) has been included in the structural model. South of the Tauern window (distance interval 400–480 km), the upper crust shows little lateral variation with velocities of 5.9 km s^{-1} near surface to 6.2 km at 15 km depth. The southward dip of the boundaries to the middle crust and lower crust continues from the Bohemian Massif at 200 km along the profile to approximately the Periadriatic line (PAL), the boundary to the Southern Alps at profile distance 440 km. However, no structural elements in the crust can be correlated with the PAL. Beneath the Eastern Alps, the Moho dips more steeply to the south than in the north and reaches a maximum depth of 47 km under the PAL. Lower crustal velocities increase to 6.5 km s^{-1} in this area.

At the PAL, the Moho depth decreases from 47 to 42 km. The Moho is again well resolved by P_mP and P_n arrivals, decreasing slightly from 42 km to 40 km toward the south. A midcrustal reflector south of the PAL at ~32 km depth is not as pronounced as comparable structures in the northern part of the profile. The velocity model of the upper crust changes abruptly at the transition to the Dinarides and the Adriatic foreland (distance ~480 km, Figure 12(a)). High basement velocities between 6.2 and 6.4 km s^{-1} extending down to 6 km depth are underlain by a low-velocity zone (LVZ) with velocities <6.2 km s^{-1} that extend down to ~17 km. Lower crustal velocities range from ~6.4 to 6.5 km s^{-1}. The dip of the velocity boundaries and contours is predominantly zero. A reduction in P_mP phase arrival times of >2 s at critical distances indicates a shallower Moho depth (~28 km) at the southern termination of Alp01. The velocity in the uppermost mantle determined from P_n travel times is 8.15–8.25 km s^{-1} below the Bohemian Massif, the Molasse basin, the Eastern Alps and Southern Alps, and the External Dinarides. The velocity in the shallow mantle at the southern end of Alp01 (8.1 km s^{-1}) follows only from amplitude modeling of P_mP and should not be compared with the other values. A lower lithospheric reflector is well resolved between profile distances of 300–440 km. It lies ~25 km below the Moho and parallels the southward dipping Moho in this part of the profile. It is below the depth range of Figure 12(a).

The crustal structure along the Alp02 profile (Figure 12(b)) reflects two completely different tectonic styles: collision within the Eastern Alps in the west and extension to the east in the Pannonian Basin (Internal Dinarides and Tisza unit). These two realms are separated by a transition zone below the Southern Alps in the distance range of 220–340 km. Between 100 and 300 km, Alp02 approximately follows the PAL (Figure 1).

The sedimentary layers in the narrow valleys and small basins of the Eastern Alps are not resolved by the ALP 2002 data. Individual depressions in the Pannonian Basin (e.g., Sava Depression) along Alp02 are 1–3 km deep according to the data from hydrocarbon exploration efforts (Saftić et al., 2003). The uppermost basement along the whole profile is

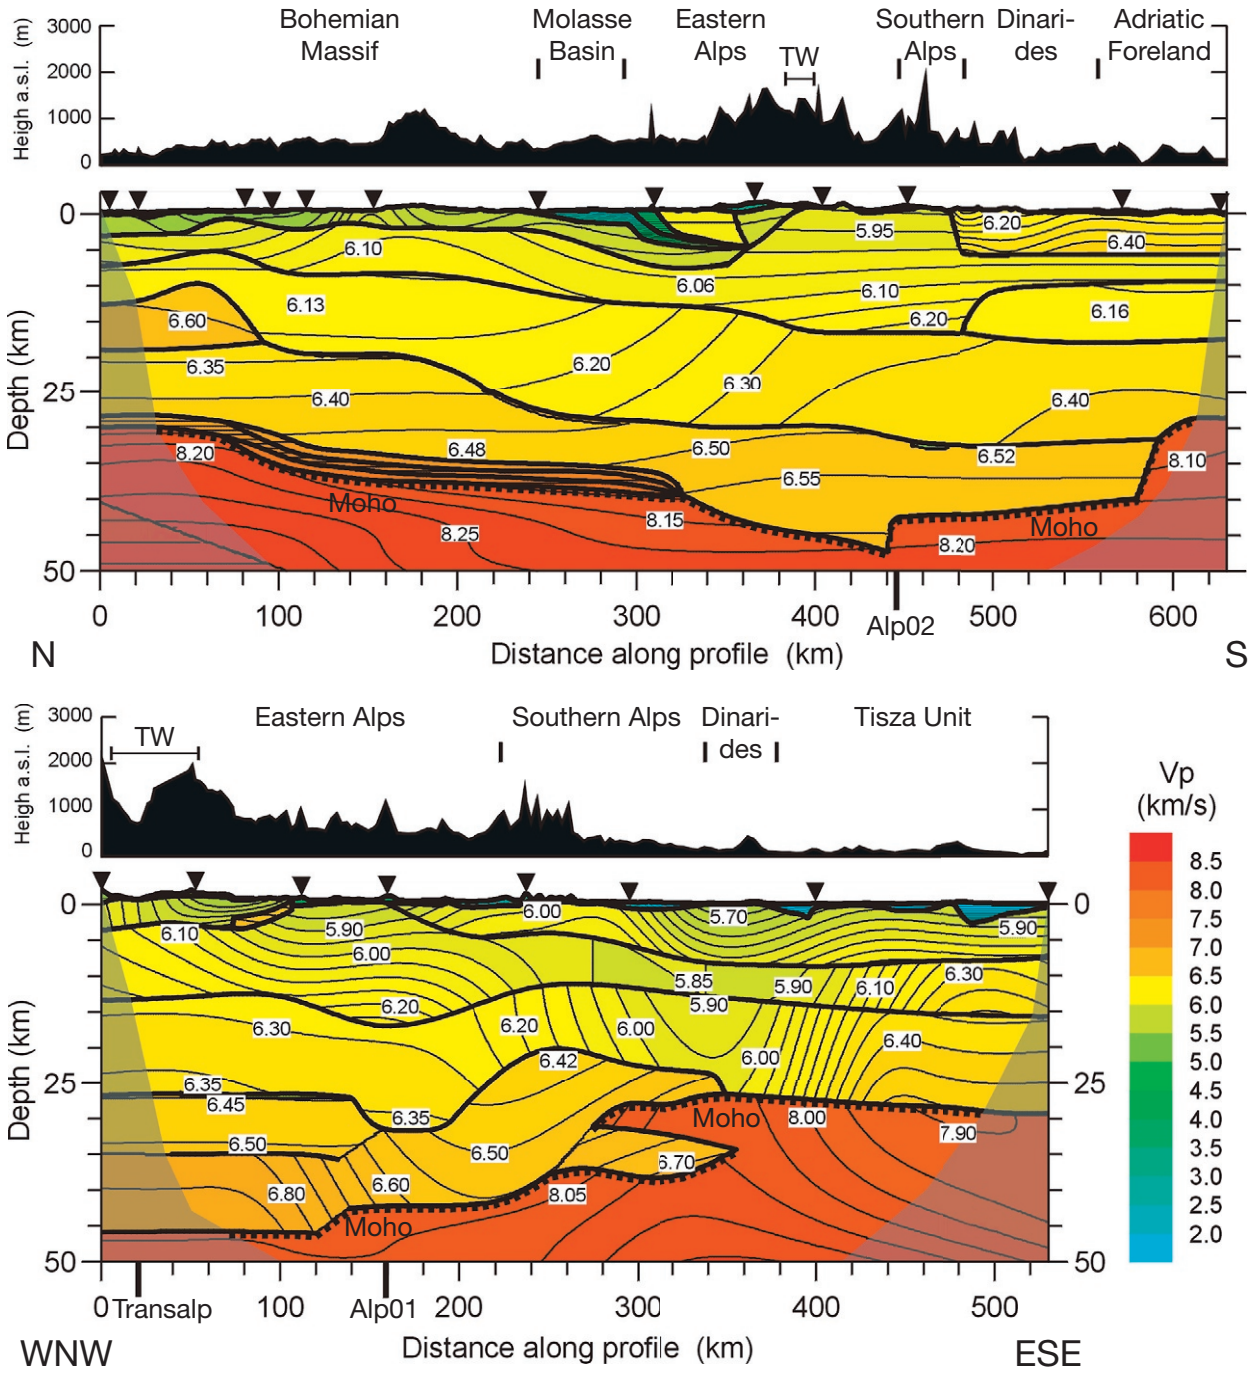

Figure 12 Two-dimensional P-wave velocity models for the ALP 2002 profiles Alp01 and Alp02 derived by forward ray-tracing modeling using the SEIS83 package (Červený and Pšenčík, 1983). The thick solid lines are layer boundaries and thin lines are isovelocity contours in km s^{-1}; triangles refer to shot points. The Alp01 profile extends from the Bohemian Massif in the north, over the Molasse basin, the East Alpine units, and the Tauern window (TW), across the Periadriatic line (PAL), to the Southern Alps, the Dinarides, and the Adriatic foreland in the south. Note the jump from the European Moho to the Adriatic Moho below the PAL. The Alp02 profile extends from the TW in the northwest over the Eastern and Southern Alps to the Dinarides and the Tisza unit, which represents the Pannonian domain. Note the significant Moho jump with an interpreted crocodile structure at the transition from the Alpine to the Pannonian region. Vertical exaggeration for both models is ~3.7. Modified from Brückl E, Bleibinhaus F, Gosar A, et al. (2007) Crustal structure due to collisional and escape tectonics in the Eastern Alps region based on profiles Alp01 and Alp02 from the ALP2002 seismic experiment. *Journal of Geophysical Research* 112: B06308, http://dx.doi.org/10.1029/2006JB004687.

characterized by velocities of about 5.7–5.9 km s^{-1}, with the exception of a west-dipping thin slab between 80 and 110 km profile distance. This slab has a high velocity (~6.6 km s^{-1}) and extends down to about 3 km depth. Although the thickness of this slab is somewhat ambiguous, its high velocity and western dip are well constrained by reversed first-arrival observations from the neighboring two shot points. All across the model in the depth range of 10–30 km, velocities range from 5.8 to 6.5 km s^{-1}. The lowest velocities (distance 300–400 km) coincide with the transition from the collisional regime to the extensional regime in the area of the Internal Dinarides. The relatively high velocities at mid- and lower crustal levels characterize the Tisza unit. In the Eastern Alps, strong reflections from a depth of about 26 km to 35 km depth were modeled as 'floating reflectors' with velocity contrasts of 0.3–0.4 km s^{-1}. Lower crustal velocities in the Eastern Alps range from 6.45 to 6.85 km s^{-1}, slightly higher than beneath the N–S-oriented Alp01 and TRANSALP profiles (Bleibinhaus and Gebrande, 2006) in the same area. This result may indicate anisotropy in the lower crust.

From the west end of Alp02 to a distance of about 120 km, fragmentary P_mP phases suggest that the Moho is at a depth of ~46 km in agreement with the TRANSALP profile (Bleibinhaus and Gebrande, 2006; Lüschen et al., 2006). The Moho rises to a depth of 43 km near the intersection with Alp01 and rises again at 220 km profile distance. The Moho depth decreases abruptly to 27–29 km below the transition from the Southern Alps to the Pannonian Basin. A 'crocodile-like' structure with a velocity inversion was introduced in order to model amplitudes of P_n phases, which fade significantly from the Pannonian domain to the west. The shallow Moho is well constrained by P_mP and P_n phases and persists to the east end of Alp02. Velocities of the uppermost mantle are constrained by P_n phases from the intersection with Alp01 (8.05 km s^{-1}) to the east end of the Alp02 profile (7.9 km s^{-1}).

The velocity structures of Alp01 and Alp02 agree well in the area of the Eastern Alps. Differences concern only the structure of the nappe stack and the velocities of the lowermost crust. However, the velocity structures of Alp01 and Alp02 in the area of the Southern Alps and Dinarides differ significantly because the tectonic regimes are so different: collision (Alp01) and escape or extrusion tectonics (Alp02).

1.17.4.5 Examples of 3-D Tomographic Modeling

The volume of data collected in all POLONAISE'97, CELEBRATION 2000, ALP 2002, and SUDETES 2003 is huge, and it has been a challenge just to analyze the data thoroughly in profile form. However, our ultimate goal is full 3-D analysis such as the one undertaken by Środa et al. (2002) for the POLONAISE'97 data. As a smaller-scale example, here, we show some results from the study of the P5 profile region of POLONAISE'97 (**Figures 13** and **14**; Czuba et al., 2002). The geometry of recordings in the area of the P5 profile and examples of record sections are shown in **Figure 13** (only ~15% of ray paths are shown). The tomographic inversion package of Hole (1992) uses an efficient method of determining the seismic velocity distribution in a 3-D medium using first arrivals only. The velocity model is defined via a rectangular grid with equidistant nodes. The travel times are calculated using the finite difference algorithm of Vidale (1990) and adapted for media with high-velocity contrasts by Hole (1992). The ray paths are traced from the receiver back to the source along the maximum travel time gradient curves. The method of calculating slowness perturbations along the ray is described in detail by Hole (1992). This procedure is iteratively repeated until a model satisfying travel time data at a satisfactory level is obtained (0.1–0.2 s).

For the tomographic modeling of the entire POLONAISE'97 data set, 10 950 picks of first arrivals were used. The P-wave velocity of the model was defined using a distance between nodes (cell size) of 2 km. This resulted in a model whose dimensions (X, Y, Z) were $928 \times 368 \times 68$ km^3 or $464 \times 184 \times 34$ cells that covered the entire area of the POLONAISE'97 experiment. The total number of cells in the model was 2 902 784. Here, we will show results for the region of the P5 profile, which extends from 550 to 700 km in the X-direction, from 50 to 250 km in the Y-direction, and to a depth of 68 km (Z).

Only picks from offsets of less than 40 km were employed in the first step of computation. In the subsequent steps, this distance was increased in order to gradually enlarge the maximum depth of ray penetration. This approach allows the shallow layers to be constrained first before modeling the deeper ones. In each step, several iterations were nested with decreasing size of the smoothing area (Hole, 1992). In this way, the resolution of the algorithm was gradually increased. In each loop, several iterations were calculated.

Examples of results of the 3-D tomographic inversions in the area of the profile P5 (Czuba et al., 2002) are shown in **Figure 14**. Results for the entire POLONAISE'97 area along with resolution tests can be found in Środa et al. (2002). A specific feature that emerged in the analysis of the P5 area was a high-velocity body discovered in the 2-D modeling. Further definition of this feature was one goal of the 3-D modeling, and the shape of this shallow body is clearly seen in the vertical cross sections (Y, Z) and horizontal slices (X, Y) in **Figure 14**. A deeper high-velocity body was detected in the distance range of 80–120 km and at a depth >10 km. This body spatially corresponds to the Biebrza complex or the Pisz intrusion (Pi; see basement geology map in **Figure 14**). The deeper structure could only be resolved with the 3-D data and shows a crust that thickens from about 42 to 45 km southeastward.

1.17.5 Geotectonic Models of the Transition from the EEC to the Eastern Alps, Carpathians, and Pannonian Basin

Although data analysis and interpretation of the results of the POLONAISE'97, CELEBRATION 2000, ALP 2002, and SUDETES 2003 will continue, the findings to date have shed considerable light on efforts to construct structural and geotectonic models of the region. Many new results were compiled to produce Moho maps of Central Europe (Jensen et al., 2002) and the first digital map of the whole European plate (Grad et al., 2009a). Some of the results of the Central Europe experiments are discussed later.

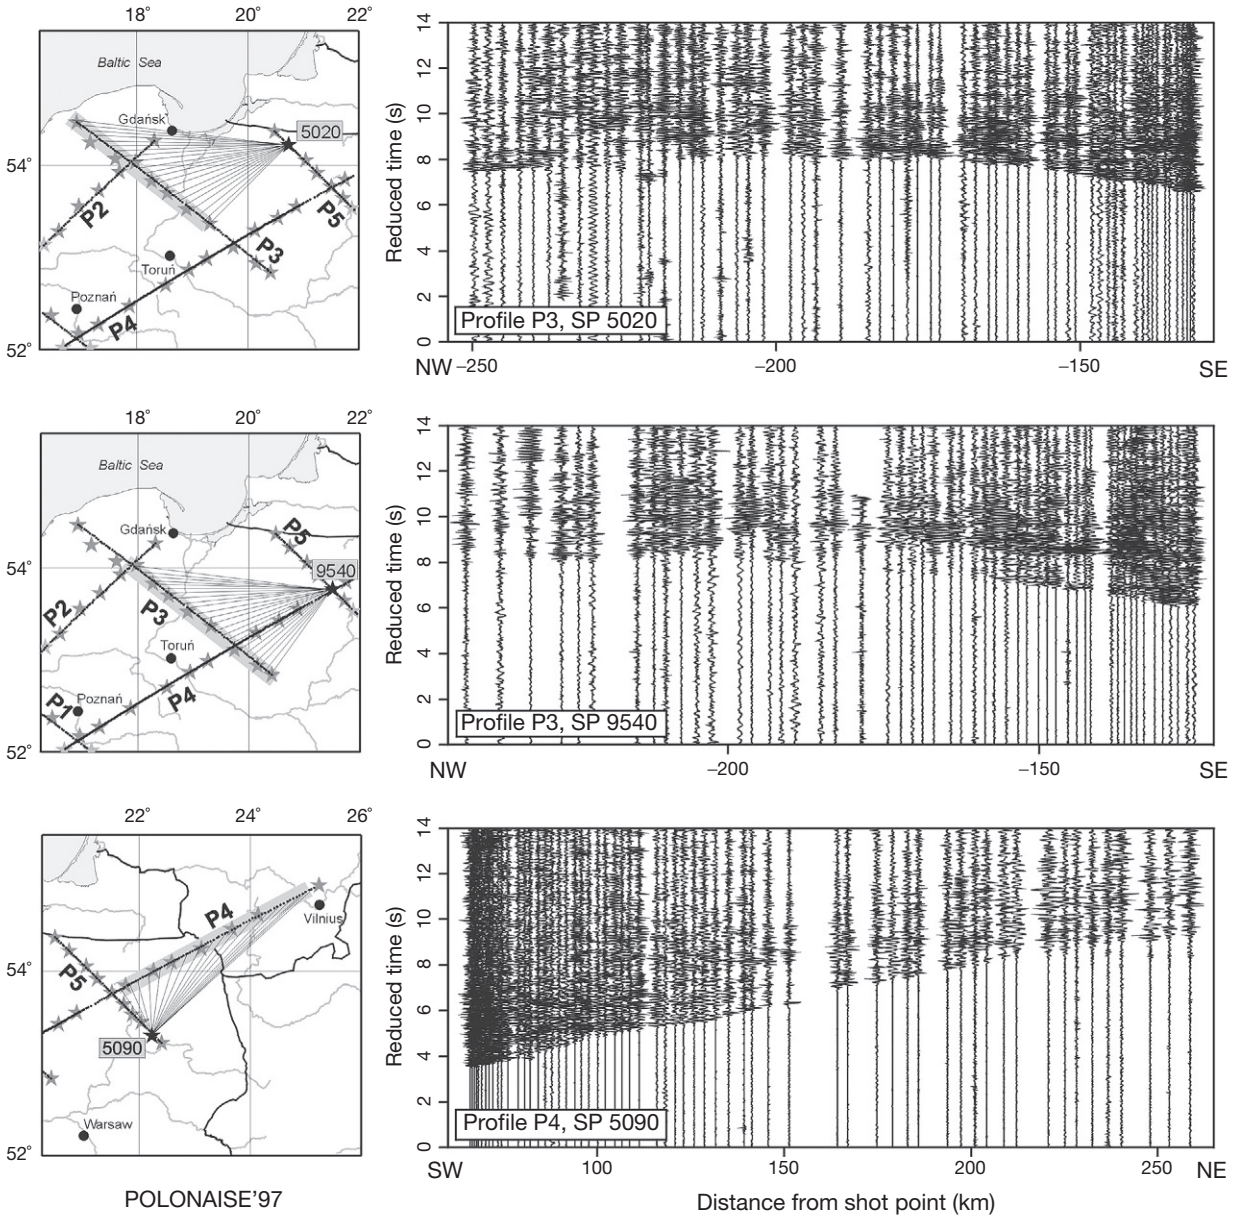

Figure 13 Examples of seismic record sections recorded in 3-D geometry during the POLONAISE'97 experiment in NE Poland and Lithuania.

1.17.5.1 POLONAISE'97 Area

The area of the POLONAISE'97 experiment represented here by P4, P1, and P3 profiles (Figure 2) and crustal/lithospheric models in Figures 6–8 has experienced several major tectonic events including the following: (1) assembly of terranes during the Precambrian to form the cratonal block that included Baltica; (2) rifting during the breakup of Rodinia/Pannotia to form the southwest margin of Baltica (EEC) in the Neoproterozoic; (3) collision between Baltica, the microcontinent eastern Avalonia, remnant ocean crust, and other terranes causing accretion in the Ordovician and early Silurian time; (4) further deformation and terrane accretion during the Variscan orogeny in the late Paleozoic; (5) extension and magmatism in the Permian and Triassic time; and (6) tectonic inversion during the Alpine orogeny in the Late Cretaceous (Figure 1). The results of POLONAISE'97 have shed considerable light on the structure and tectonic evolution of the TESZ region. However, there remain several possible explanations about how these tectonic events are reflected in the observed crustal velocity structure.

At the margin of Baltica (EEC), the upper crustal structure is clearly discontinuous because of the ~20 km deep basin present (Figures 6 and 8). It seems clear that a major consideration in developing geotectonic models for the TESZ in the region of profile P4 is whether the deep crustal layers are continuous or discontinuous beneath the deep basin. The velocities of the middle crust and lower crust do not change as significantly along the model as in other areas to the northwest where the European Geotraverse crosses Germany and the

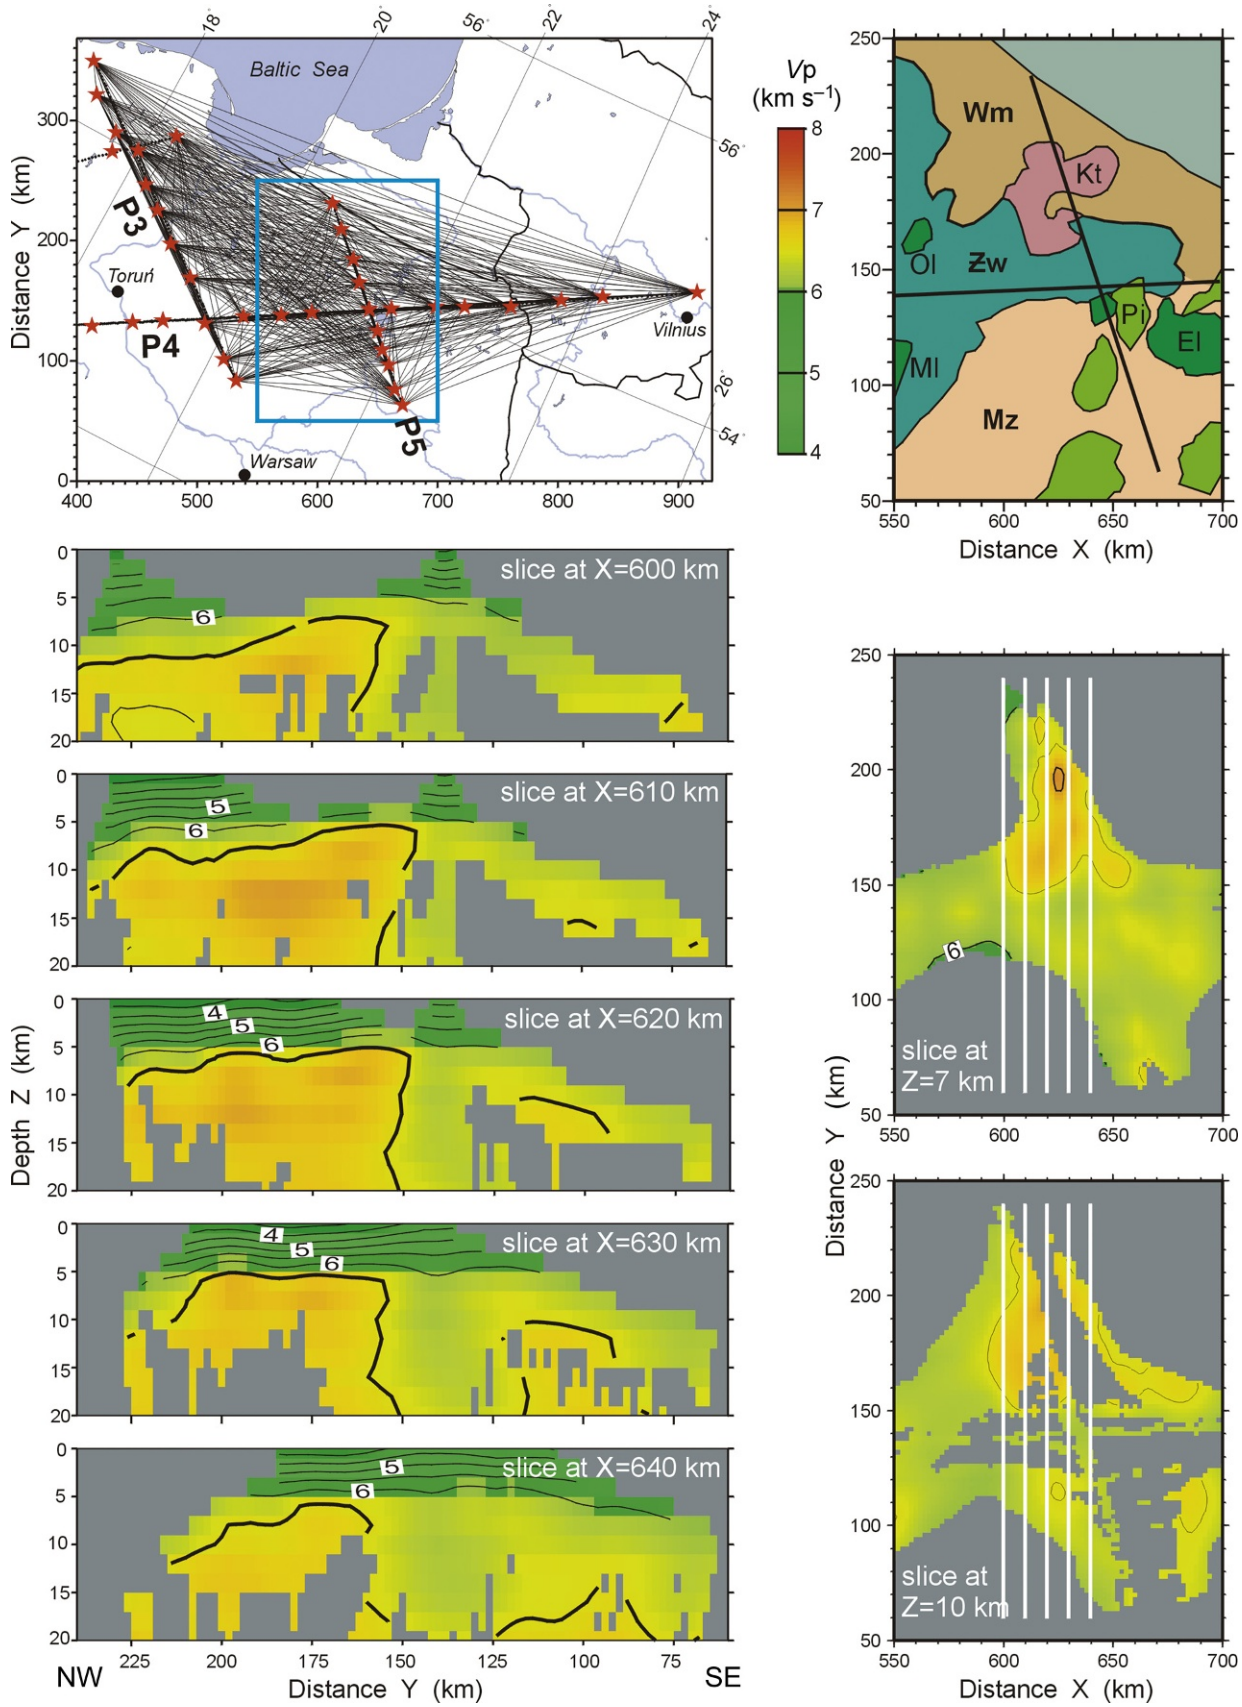

Figure 14 Results of 3-D investigations in NE Poland in the area of POLONAISE'97 profile P5 (Czuba et al., 2002). The location map shows the area of investigation as a subset of the 3-D model by Środa et al. (2002); geographic coordinates are shown on the top and right. Lines show schematic ray paths connecting shot points and recording stations, but only ~15% of the ray paths used in inversion are shown. The blue rectangle marks the area of the map of the EEC crystalline basement and area of the horizontal slices for the depths 7 and 10 km. Vertical cross sections through the model for $X = 600$, 610, 620, 630, and 640 km are also shown, and in them, the thick lines are 6.5 km s^{-1} velocity isolines. Abbreviations in the basement map: El, Ełk intrusion; Kt, Kętrzyn anorthosite intrusion; Ml, Mława intrusion; Mz, Mazowsze massif; Ol, Olsztyn intrusion; Pi, Pisz intrusion; Wm, Warmia branch; ZW, Żuławy branch.

MONA LISA experiment covered much of the southeastern North Sea. In Northern Germany, a high-velocity middle crust and lower crust to the north terminates abruptly at the Elbe Line (Aichroth et al., 1992; Thybo, 2001). In the MONA LISA lines, the termination of Baltica in the lower crust appears as a transition from high (>7.0 km s^{-1}) velocities in Baltica crust to low velocities (<6.4 km s^{-1}) in the 'pure' Avalonian portion of the crust (Abramovitz and Thybo, 2000; Abramovitz et al., 1998). Thus, a possible interpretation is that highly extended Baltican lithosphere extends as far west as 60–80 km at the P4 profile. However, based on similarities with many crustal models across both modern and ancient passive margins (e.g., Holbrook et al., 1994; Keller and Hatcher, 1999; Mickus and Keller, 1992), a more likely scenario is that the pre-Permian portion of the 20 km deep basin is a passive margin sequence that includes some units related to transcurrent motions along the margin between the initial rifting and the Variscan orogeny as shown in **Figure 15(a)**. An important piece of evidence for this being the case is drilling data, which show that a maximum of only about the upper 40% (8 km) of the fill in the Polish Basin is Permian or younger in age (Scheck-Wenderoth and Lamarche, 2005). A rift sequence should taper away from the EEC margin, but this is only partially the case in the seismic model (**Figure 15(a)**). However, to the southwest toward the Bohemian Massif region, there are thrust faults and synorogenic sedimentary rocks (OS in **Figure 15(a)**) that would fill this portion of the basin. An obvious for argument for extension is that the crystalline crust beneath the basin is half as thick as the crust under the adjacent EEC (**Figure 15(a)**). In addition, Janik et al. (2005) discussed the evidence indicating that this margin experienced translation of crustal blocks in the Paleozoic subsequent to its formation that could create a pull-apart basin. The abrupt change in structure at the margin of Baltica is also evidence that transtension was involved in the initial rifting as has been argued for the case of the Ouachita orogenic belt of the Southern United States (Mooney, 2015; Thomas, 1991).

The deeper structure southwest of the deep basin reflects the collision between Baltica and Avalonia/Bohemian Massif. The geometry of the crust and upper mantle in this area (**Figure 15(a)**) has similarities with BABEL line A in the southern Baltic Sea (BABEL Working Group, 1993). Thus, Baltica and its margin can be viewed as the indenter in the collision with the crust of the Variscan region being driven upward onto the margin of Baltica and the Variscan mantle being driven beneath the margin of Baltica. The fact that the passive margin appears to be largely intact and the lack of late Paleozoic deformation within Baltica indicates that collision was relatively soft.

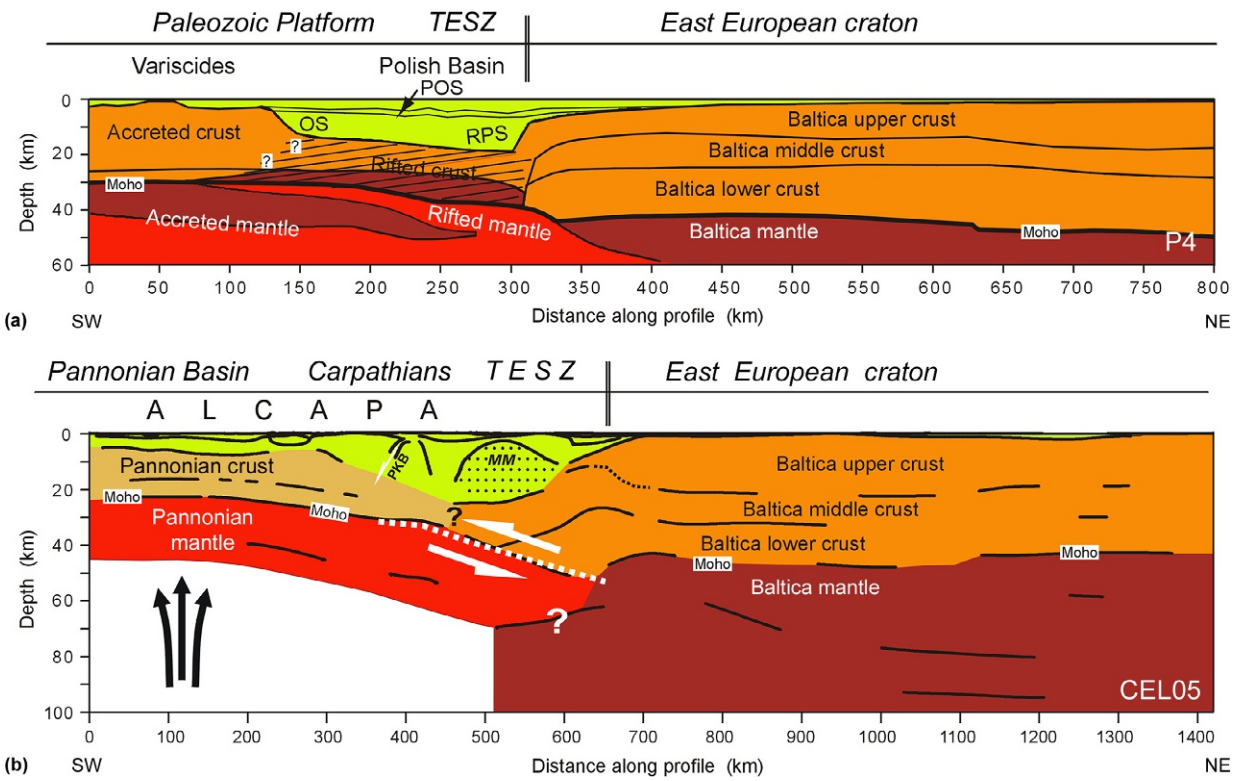

Figure 15 The representation of a tectonic interpretation of the transition between Baltica (EEC) and the adjacent accreted terranes (Paleozoic platform) in the TESZ area along profile P4 (a) and the transition between the Pannonian Basin and EEC along profile CEL05 (b). The model for profile P4 (a) is modified from Grad et al. (2003a) and shows an abrupt transtensional margin where the southwestern extent of Baltica lithosphere is minimal. POS, post-orogenic sedimentary sequence; OS, orogenic sedimentary sequence; RPS, rift (pull-apart) sedimentary sequence. The model for profile CEL05 (b) is modified from Grad et al. (2006) and shows the 'old' (northward) subduction zone of the Pannonian lithosphere under EEC in the Jurassic–Lower Cretaceous (Książkiewicz, 1977) or by the end of the Jurassic, ~140 Ma (Golonka et al., 2003a). 'Young' (southward) subduction of the EEC lithosphere in the Tertiary (Miocene) is represented by the Pieniny Klippen Belt (PKB).

In conclusion, the observed structure along profile P4 (Figures 6 and 15(a)) indicates that rifting and subsequent transtension created an abrupt margin for Baltica along which a thick (~10 km) sedimentary sequence was deposited. In addition, the seismic model suggests that the Variscan orogeny was a soft collision in which the margin of Baltica acted as an indenter.

1.17.5.2 CELEBRATION 2000 Area

The velocity model derived for the CEL05 profile provides an important new view of lithosphere across the Carpathian–Pannonian region and transitions with the EEC (Baltica). The Mesozoic and Cenozoic tectonic environments of this region involved complex conference between the European and Adriatic plates and a variety of intervening microcontinents and oceanic areas (e.g., Golonka et al., 2003a,b), and many aspects of the tectonic evolution remain controversial.

Our preferred tectonic interpretation of the velocity model (Figure 10) is shown in Figure 15(b). The southwestern end of CEL05 begins in the Tisza–Dacia block, which is separated from the ALCAPA block to the north by the Mid-Hungarian line (Figure 1) (e.g., Bielik et al., 2004, 2010; Szabó et al., 2004). The western Pannonian Basin and Inner Carpathians are part of the ALCAPA block that extends northward to the PKB. Our model is in agreement with previous studies in the region (e.g., Posgay et al., 1995; Royden and Dövényi, 1988) in showing that the Pannonian Basin is characterized by a thin (~25 km) crust and 2–3 km of Tertiary sedimentary and volcanic cover. Two important observations are as follows: (1) the crust below this cover has a low average velocity (~6.1 km s^{-1}), indicating that it is not oceanic in nature (Grad et al., 2006), and (2) there is no large change in lithospheric structure across the Mid-Hungarian line, which suggests that extension and magmatism associated with the formation of the Pannonian Basin has modified the lithosphere considerably.

In contrast to the Pannonian Basin region, the structure of the upper crust becomes more complicated along the profile as it traverses the Inner Carpathians, PKB, Outer Carpathians, and Carpathian Foredeep. The observed velocity structure is in good agreement with the surface geology and drilling results such as the deep drill holes near Wysowa (Figure 10). The south-dipping body that correlates with the PKB attests to the importance of this feature. From a deeper perspective, the crust gradually thickens into and across the Carpathians up to the margin of the EEC, and the mantle reflectors deepen to remain parallel to the Moho.

Near the margin of the EEC, the profile crosses the MM, Radom–Kraśnik uplift, and Lublin Trough before passing into the relatively undisturbed EEC crust that is typical of that found in other nearby areas (Figure 10). Because it is a large crustal block that may be exotic with respect to the EEC, the MM has been the subject of much interest and several interpretations. Geologic studies reveal folded metasediments of the Vendian–Early Cambrian age at depths that are covered by younger strata. However, drilling data and the new POLONAISE'97 and CELEBRATION 2000 results suggest that it was probably once a part of Baltica and was detached and then moved to its present location (Dadlez et al., 1994, 2005; Janik et al., 2005). The MM is bounded on the north by the Radom–Kraśnik uplift that is in turn bounded in the south by the Lublin Trough (Figure 10), and the crustal structure beneath these features is complex. More geologic data are needed to access the implications of these observations.

Northeast of the Lublin Trough, the profile crosses the EEC where a relatively simple structure is observed. However, the Precambrian history of the cratonal area is complex, having been interpreted as involving the accretion of three terranes: Fennoscandia, Sarmatia, and Volgo-Uralia (Bogdanova, 1996; Bogdanova et al., 2001). In western Belarus, profile CEL05 approximately follows the suture between Fennoscandia and Sarmatia, which is marked by the Mazury–Belarus orogenic belt (Figure 10). A change in lower crustal structure and upper-mantle velocity occurs in the vicinity of this interpreted suture, implying that it is a major lithospheric boundary.

As discussed by Grad et al. (2006), several large-scale tectonic interpretations are possible for the CEL05 velocity model. The most surprising feature in this model is the northward dip of the Moho and mantle reflectors beneath the Carpathians and the region of the EEC margin that suggests northward subduction (Figures 10 and 15(b)). This observation is at odds with the known surface geology such as the south-dipping PKB that indicates that Cenozoic subduction was to the south. However, several workers have suggested that northward subduction occurred in the Mesozoic (Golonka et al., 2003a; Książkiewicz, 1977), so subduction in the region could have flipped. However, the lack of a Mesozoic arc to the north indicates that any northward subduction would have been short-lived. A lithospheric-scale 'crocodile' structure with Baltica acting as the rigid indenter could also produce south-dipping features in the upper crust and north-dipping deep structures during Cenozoic convergence. Finally, a thermal anomaly and extension in the Pannonian Basin area would cause crustal thinning, producing an overall appearance of northward dip (Grad et al., 2006). Add in the complexities of large-scale strike-slip movements (e.g., Csontos and Vörös, 2004) and slab rollback to the east (Seghedi et al., 2004; Wortel and Sparkman, 2000), and it becomes difficult to make definitive tectonic interpretations. However, recent petrologic studies (Trua et al., 2006) indicate that Precambrian lithospheric mantle is present beneath the PKB region, suggesting that slab rollback did not grossly alter the lithospheric structure of this region, which implies at least some of the northward dip observed is probably old.

A third model explains the observed structure as the result of 'young' (Miocene) southward subduction of Variscan and EEC lithospheres and of Neogene thinning of the Pannonian lithosphere due to extension. Our data show no evidence of a south-dipping slab in the upper mantle or south-dipping features in the lower crust from the Carpathian Foredeep southward. However, one could imagine the south-dipping features adjacent to the EEC (500–700 km) being attached to a south-dipping slab that has broken off and either sunk to great depth or been absorbed.

In summary, the seismic model for the 1420 km long profile CEL05 targeted the Pannonian Basin, the Carpathians, the TESZ, and the EEC. Given the complex geologic history of the region, the equally complex velocity structure is no surprising. The CEL05 results indicate that two episodes of subduction with different polarities are possible. These results also provide

considerable information on the deep structure and relationships between upper crustal features known from drilling and geologic data. However, further integrated geophysical and tectonic analyses will be required to fully determine the implications of the CELEBRATION 2000 data.

1.17.5.3 ALP 2002 Area

The dense source and receiver layout along the CELEBRATION 2000 and ALP 2002 profiles (Figure 2) and the 3-D aspect of data acquisition (cross-line shooting) provided new data that make the construction of a well-constrained Moho map in the East Alpine–Pannonian realm possible. The Moho reflects the structure of the lithospheric mantle and the interpretation of its structure in a plate tectonic context is a challenging task. Destructive plate boundaries can be identified by offsets of an otherwise smooth Moho boundary derived from controlled source seismic data (e.g., Abramovitz and Thybo, 2000; Kissling et al., 2006; Waldhauser et al., 1998). However, continental transform or strike-slip faults may exist without significant offsets of the Moho boundary and are thus difficult to identify (Thybo et al., 2003; Weber et al., 2006, 2009; Zhao et al., 2001).

The Moho map shown in Figure 16(a) is based on the European Moho map of Grad et al. (2009a). In the Alpine area, it was edited by inserting the more detailed Moho map of Behm et al. (2007). Stacking of refracted and reflected P-waves recorded during the CELEBRATION 2000 and ALP 2002 experiments were combined with tomographic inversion of Pn arrivals to generate this map. In the west, data from the TRANSALP transect were also included (Bleibinhaus and Gebrande, 2006; Bleibinhaus et al., 2006; Lüschen et al., 2006). The location and shape of the Moho at plate boundaries were refined by elastic plate modeling of the lithosphere east of 11° E by Brückl et al. (2010). In the western portion of the map, the depth and offset of the Moho at these boundaries determined by Waldhauser et al. (1998) were included. ALP 2002 seismic data and gravity interpretations improve the resolution of the boundary between Adria and the Pannonian domain (Šumanovac, 2010; Šumanovac et al., 2009).

The resulting Moho map indicates a fragmentation of the mantle lithosphere into three blocks: the European plate (EU), the Adriatic microplate (AD), and a newly interpreted 'Pannonian fragment' (Behm et al., 2007; Brückl et al., 2007). In the following discussion, we use the term 'Pannonian domain' (PA), rather than 'Pannonian fragment.' This domain comprises the mantle lithosphere below ALCAPA, Tisza, and the Dinarides. The three blocks, EU, AD, and PA, constitute a triple junction (Figure 16(a)). The clear Moho offset on profile Alp02 (Figure 12) at a distance 300 km and a second order discontinuity in the Moho map (shown as a southeast-trending dashed plate boundary in Figure 16(a)) coincide approximately with the boundary between the Dinarides and the Tisza unit. ALCAPA (Alps–Carpathians–Pannonian) units are clearly separated from the Dinarides and the Tisza unit by the Periadriatic line (PAL) and the Mid-Hungarian line (MHL) on the surface. However, the Moho structure east of the triple junction does not clearly reflect this boundary in the lithospheric mantle, probably because of its strike-slip nature and the high-temperature regime in the Pannonian upper mantle.

Images of the upper mantle supplied by seismic tomography contribute to a better understanding of plate tectonic processes and support the interpretation of the Moho structure. We include the P-wave models of Koulakov et al. (2009), Dando et al. (2011), and Mitterbauer et al. (2011) into our tectonic interpretation. These models cover the area around and east of the Alp01 profile (Figure 2). We averaged these models with equal weights within their areas of high resolution and show the $dV_P = 1.4\%$ contour at 180 km depth in Figure 16(a). This contour delineates the extent of the East Alpine continental lower lithospheric slab (EAS). The triple junction between the three blocks is located near the southeastern termination of the Tauern window and coincides well with the eastern termination of the EAS. No high-velocity bodies, which could be associated with continental slabs, exist along the EU–PA boundary and the PA–AD boundary north of 45° N.

Figure 16(b) provides a 3-D visualization of a generalized tectonic interpretation of the Alp01 profile (A–B), the mantle lithosphere of EU and AD (represented by schematic 60 km thick plates), and the averaged tomographic model, represented by three orthogonal slices through the d*V*p volume (dV_P is the deviation of the P-wave velocity from the ak135 model). The EAS is visualized by the $dV_P = 1.4\%$ isosurface. The corner points of the model (A, B, C) are marked in Figure 16(a). The crystalline basement of the Bohemian Massif (European basement) in the northern portion of the Alp01 profile represents the former passive margin of the Penninic Ocean. The upper crustal low-velocity zone (LV) north of the North Alpine thrust fault (NAT) coincides with the Molasse basin (M) and the Flysch Belt (F). It extends into the basement, indicating extensional tectonics before collision or bending during the generation of the foreland basin. East Alpine (ALCAPA) units overthrust the European basement about 150 km to the north along A–B. The Penninic (P) and Subpenninic (European) units of the Tauern window (TW) have been exhumed ~25 km (e.g., Fügenschuh et al., 1997) by thrusting and folding over a shear zone during the Miocene. This zone, the sub-Tauern ramp, was identified along the TRANSALP transect by steeply dipping reflections (e.g., Lüschen et al., 2004, 2006). The topography of the Moho and the velocity structure of the crust supply sufficient constraints to infer a tectonic style similar to the Alp01 profile. The Periadriatic line (PAL) separates the Eastern Alps (ALCAPA) from the Southern Alps (SA). Its location coincides with the Moho jump from the EU to AD. However, it cannot be traced through the crust without ambiguity, probably due to its character as a steeply dipping strike-slip fault. The general vergence of thrust faults changes from north in the Eastern Alps to south in the Southern Alps. The Dinarides (DI) and the Adriatic foreland are characterized by a high-velocity zone (HV) in the upper crust and nearly horizontal layering of the seismic velocity structure.

Crustal thickening is closely related to post-collision convergence and quantitative information can be derived from the balancing of these processes. In the area of the Tauern window, post-collision convergence and crustal thickening were considered along a cross section at 13° E from the Molasse basin in the north to the Southern Alps and the Venetian plain under the assumption that no crustal material was subducted (Brückl et al., 2010). Here, we consider the Alp01 profile at 13.5° E, shown in Figure 16(b) along A-B, in a similar manner. From the Bohemian Massif to the Tauern window, the thickness of

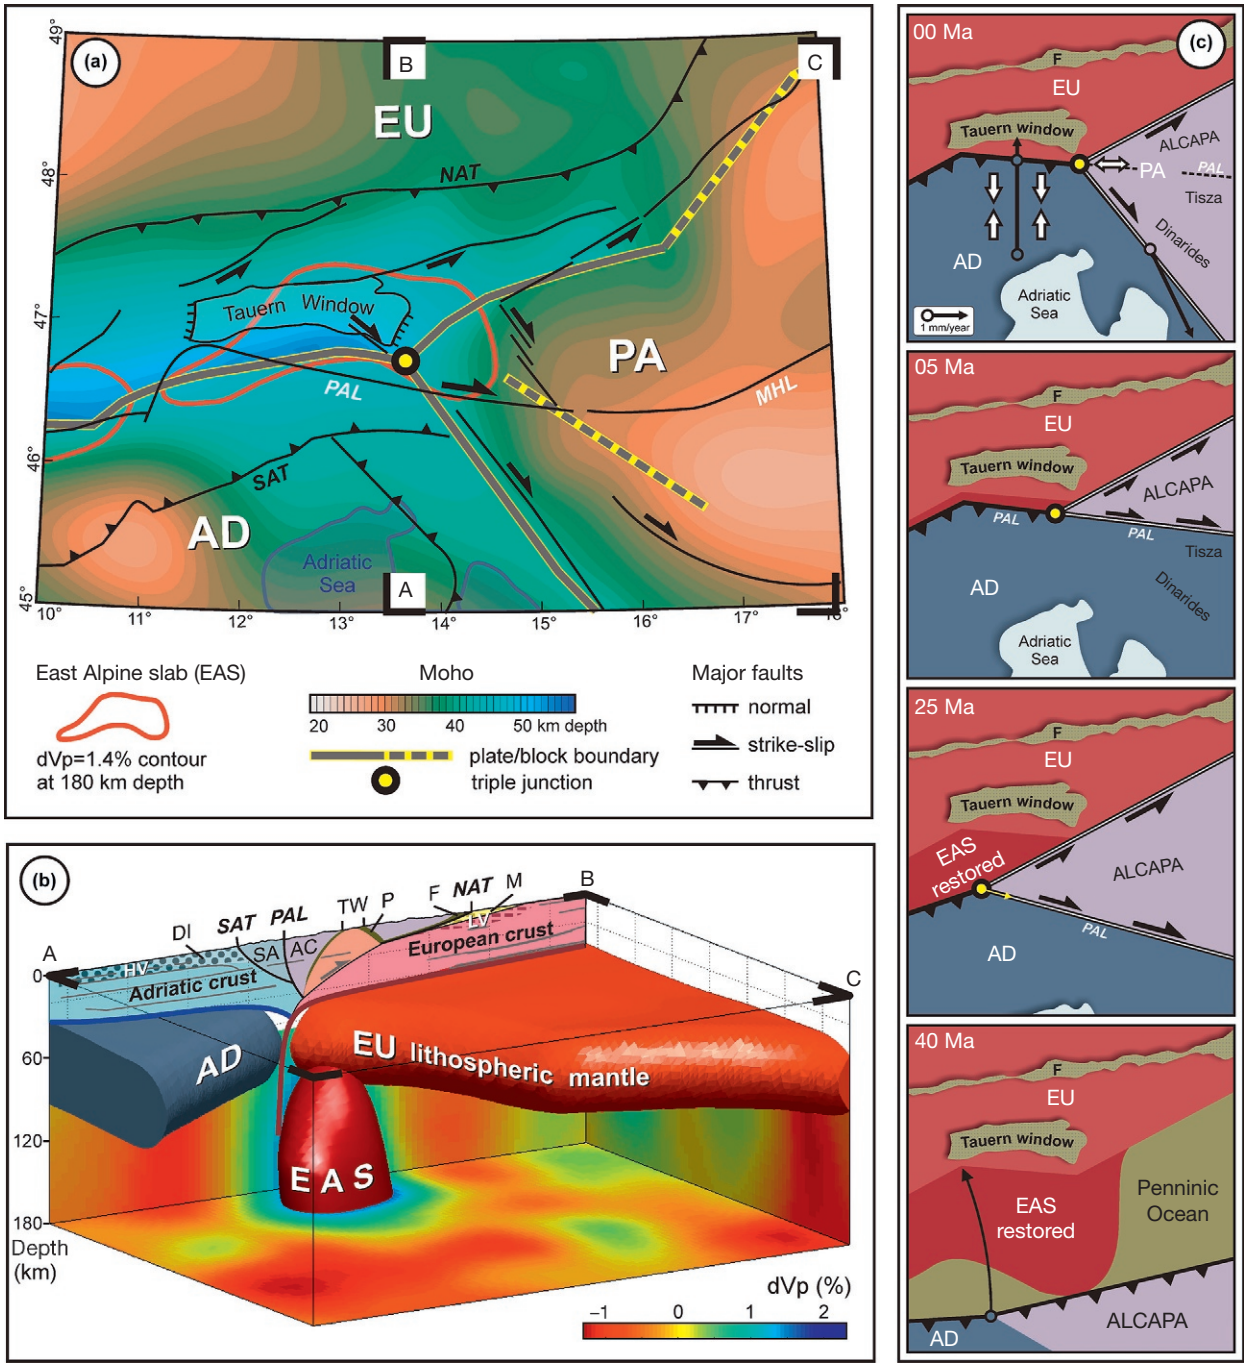

Figure 16 Structure of the East Alpine lithosphere and tectonic model of the plate tectonic evolution since Eocene. (a) Moho map showing the tectonic fragmentation into the European plate (EU), Adriatic microplate (AD), and the Pannonian domain (PA) with a triple junction southeast of the Tauren window (TW). The extent of the East Alpine slab (EAS) is marked by the $dV_P = 1.4\%$ contour at 180 km depth. Major faults (NAT – North Alpine thrust fault, PAL – Periadriatic line, MHL – Mid-Hungarian line, SAT – South Alpine thrust fault), the boundary of the Tauern window (TW) and the shoreline of the Adriatic Sea, are superimposed on the map. (b) Visualization of the East Alpine lithosphere and upper mantle east of 13.5° E. The corner points (A, B, C) of the model are also marked in the map. The generalized geologic cross section from A to B at 13.5° E approximately follows the Alp01 profile (M, Molasse basin; F, Flysch Belt; AC, East Alpine, respectively, ALCAPA units; P, Penninic units of the TW; SA, Southern Alps; DI, Dinarides). Dashes around the Molasse basin to the north and dots in the area of the Dinarides and the Adriatic foreland mark zones of relatively low (LV) and high (HV) P-wave velocities, respectively. The EU (red) and AD (blue) lithospheric mantle are represented schematically by 60 km thick slabs. The PA lithospheric mantle is not shown in order to allow for the view to the deeper EAS (visualized by its $dV_P = 1.4\%$ isosurface) and its connection to the EU lithospheric mantle. The P-wave velocity structure of the upper mantle, derived from tomographic studies, is represented by three orthogonal slices. Please see the text for a more detailed description and reference. (c) Plate tectonic reconstruction at the level of the Moho and the lithospheric mantle from the first contact of the Adriatic domain (including ALCAPA) with Europe (40 Ma) to the modern active tectonics (00 Ma). Please see the text for description.

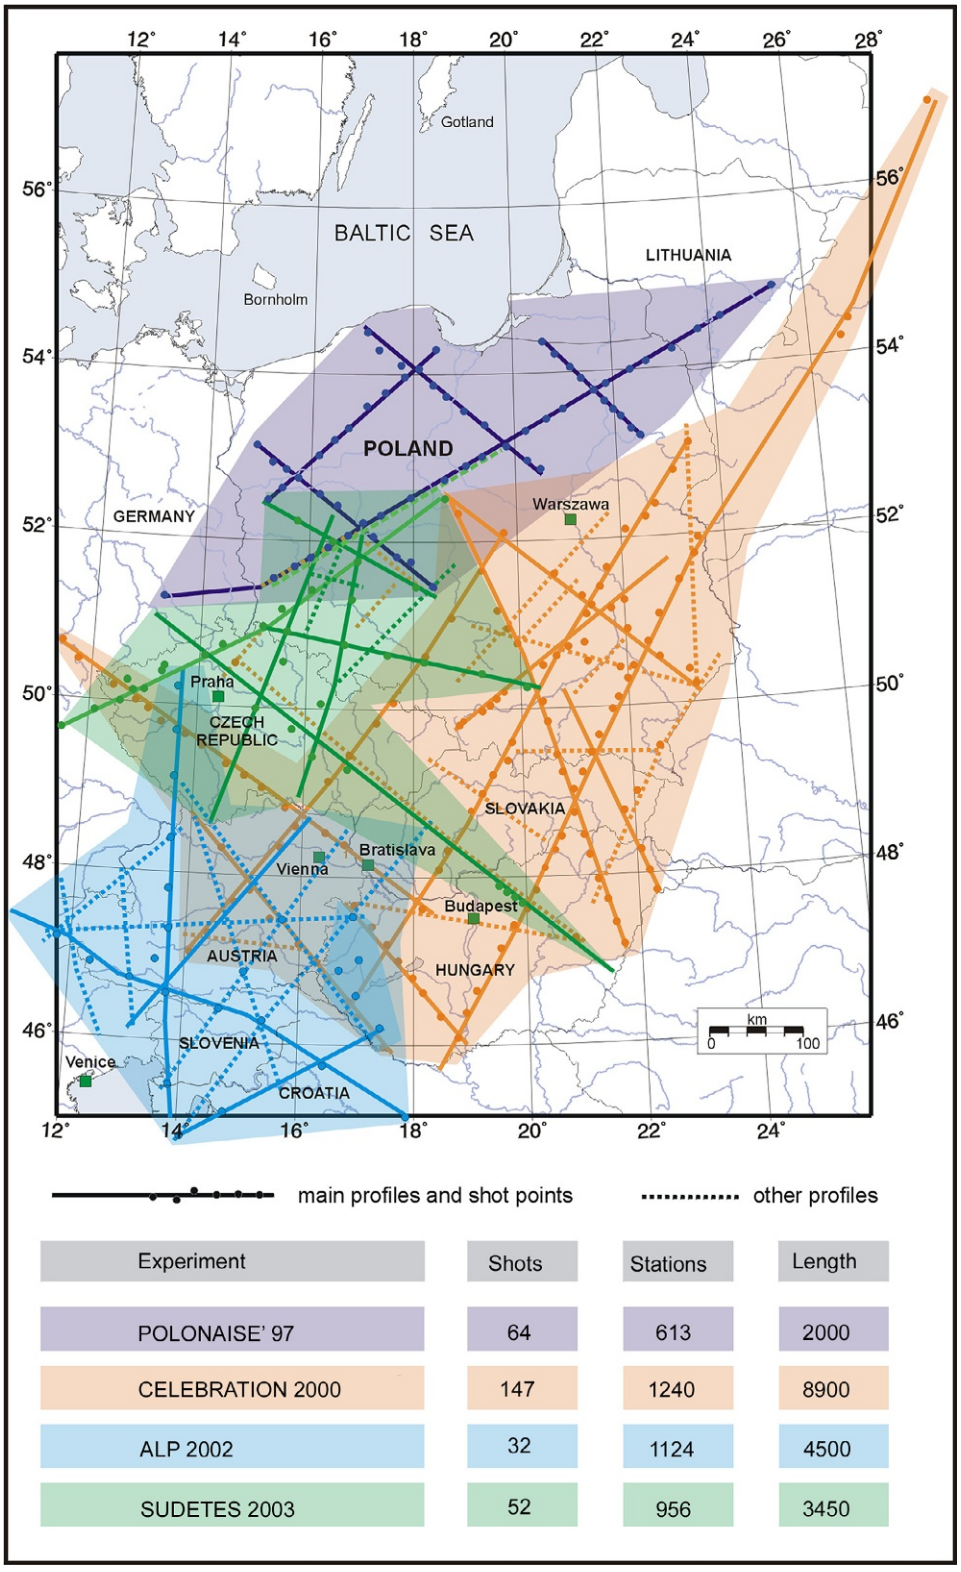
the crystalline basement diminishes by about 5 km. This thinning may be explained by the fact that the European basement constituted the passive northern margin of the Penninic Ocean. Post-collisional thickening is speculative to derive from this structural data. In the central part of the Eastern Alps, the 25 km exhumation of the Tauern window by thrusting over the sub-Tauern ramp (slope ~21° along Alp01) corresponds to a horizontal convergence of ~65 km. The average thickness of the AD crust under the Southern Alps and Dinarides is ~42 km. The major part of the thickening took place either by thrusting in the crystalline upper crust and thrusting of AD lower crust over the sub-Tauern ramp or by stacking of lower crust (e.g., Castellarin et al., 2006). Thickening of the Adriatic crust north of the Adriatic foreland corresponds to a crustal shortening of ~30 km assuming a thickness of 30 km for the pre-collision Adriatic crust.

The total north–south convergence since collision derived from crustal thickening is about 95 km. However, geologic investigations and palinspastic reconstructions arrive at significantly larger figures (165–195 km) (e.g., Fügenschuh et al., 1997; Ustaszewski et al., 2008). The difference between crustal shortening derived by cross-sectional balancing of the whole crust and retrodeformation of the upper crust is not equally distributed over the whole profile. There is a fair agreement of N–S convergence derived by both methods in the Southern Alps (Castellarin and Cantelli, 2000; Castellarin et al., 2006; Schönborn, 1999). For the Eastern Alps, the situation is significantly different. Frisch et al. (2000) derived 140 km crustal shortening at the western boundary of the Tauern window by a palinspastic reconstruction. The discrepancy between the amount of convergence and crustal thickening can be (at least partly) resolved by the assumption of an eastward-directed lateral extrusion of the central and eastern part of the Eastern Alps to the Pannonian Basin (Ratschbacher et al., 1991). Linzer et al. (2002) estimated ~120 km of E–W extension between the Brenner and Katschberg normal (west and east boundaries of the Tauern window, **Figure 16(a)**) faults during Miocene. Shortening is therefore underestimated by restoration applied in 2-D along the Alp01 profile.

We also have used the data from our experiments in an integrated analysis of the relation between crustal and upper-mantle structures. We interpret the European crust and lithospheric mantle to be connected to the East Alpine continental lower lithospheric slab (EAS), and thus identify this slab as former lower European lithosphere. This interpretation is depicted in **Figure 16(b)**, but other interpretations have been proposed. For example, based on an apparent NE-directed dip of the EAS resolved by teleseismic tomography carried out as part of the TRANSALP project, the EAS has been connected to the Adriatic mantle lithosphere (e.g., Kissling et al., 2006; Lippitsch et al., 2003), thus inferring a subduction polarity flip at about 11° E (near the Brenner normal fault terminating the TW on the west, **Figure 16(a)**) from the west to the east. However, the lithospheric kinematics of such a polarity flip are not easy to explain by standard plate tectonic models. Avoiding a polarity flip by interpreting the EAS as the EU lower lithospheric slab, as proposed among others by Brückl et al. (2010) and Mitterbauer et al. (2011), provides a kinematic interpretation constrained by fundamental plate tectonic concepts. The length of the EAS (measured from the center line of the lithospheric mantle) derived from the different tomographic models cited earlier is about 150 km. Breakoff of the subducted Penninic Ocean slab occurred before the subduction of continental slabs (e.g., Wortel and Sparkman, 2000). The remains of this slab have been imaged at depths >350 km (e.g., Dando et al., 2011; Mitterbauer et al., 2011).

Finally, we present a schematic reconstruction of the collision and extrusion processes at the level of the Moho and the lithospheric mantle from the time of the first contact of the Adriatic microplate with Europe to present day active tectonics (**Figure 16(c)**). This reconstruction is based on the geometry of the Moho discontinuities that define plate fragments and the EAS. The coincidence of the locations of the triple junction AD–EU–PA and the eastern termination of the EAS (**Figure 16(a)** and **16(b)**) constitutes the most important constraint. The absence of continental lithospheric slabs (high P-wave velocity bodies) at the EU–PA plate boundary was explained by thrusting or subduction west of the triple junction and strike-slip or transform movement east of it (Mitterbauer et al., 2011). The PAL and its continuation into the MHL experienced large displacements during collision and extrusion (e.g., Csontos and Nagymarosy, 1998; Ratschbacher et al., 1991). We assume that this deformation is represented by relative plate movements on a lithospheric scale and infers a further plate fragmentation at the Moho between ALCAPA to the north and the Dinarides and the Tisza unit to the south that was most active during the extrusion process in the Miocene. The resulting deep structure must be complex, but for simplicity, the fragmentation at the Moho is approximated by straight lines in these figures. We consider the triple junction to be stable and apply the appropriate stability conditions (McKenzie and Morgan, 1969). We keep the position of the European mantle (EU) fixed. The Flysch Belt (F) at the northern rim of the Eastern Alps, the Tauern window, and the northward-moving Adriatic Sea are superimposed on the maps for orientation. The steps in our reconstruction are as follows (**Figure 16(c)**):

A. 40 Ma – Eocene: The European passive margin of the Penninic Ocean has been restored by flipping the EAS from subvertical to its horizontal orientation before subduction. The Adriatic microplate (AD including ALCAPA) constitutes the active margin of the subducting Penninic Ocean. This continental domain rotates counterclockwise around an Euler pole at approximately 7° E, 45° N (e.g., Ustaszewski et al., 2008). The first contact with the European continent occurs south of the present day Tauern window.
B. 25 Ma – Oligocene/Miocene: The Penninic Ocean had closed completely and breakoff of the oceanic slabs was complete. The Periadriatic line (PAL) was activated and ALCAPA started to move via dextral strike-slip relative to AD. A stable triple junction is generated between EU–AD–ALCAPA. The ALCAPA – EU plate boundary turns from subduction to strike-slip, thus, avoiding the generation of a continental lithospheric slab east of the triple junction.
C. 05 Ma – Miocene–Pliocene: Convergence between AD and EU nearly reached the current state. The triple junction moved along the PAL more than 100 km to the east, and strike-slip changed to subduction along this part of the PAL. The angle between the strike-slip boundaries



Experiment	Shots	Stations	Length
POLONAISE' 97	64	613	2000
CELEBRATION 2000	147	1240	8900
ALP 2002	32	1124	4500
SUDETES 2003	52	956	3450

Figure 17 Layout of the POLONAISE'97, CELEBRATION 2000, ALP 2002, and SUDETES 2003 seismic experiments in Central Europe.

confining ALCAPA became more oblique because of the CCW rotation of AD versus EU, thus, causing west–east-oriented extension of ALCAPA. This extension in combination with the eastward movement of the triple junction substantially supports the extrusion of parts of the Eastern Alps toward the Pannonian Basin in the east.

D. 00 Ma – active tectonics: The Periadriatic line loses its significance as first-order active tectonic structure. ALCAPA,

Tisza, and the Dinarides amalgamate to form one tectonic block, the Pannonian domain (PA). Tectonic activity moved from the west–east striking Periadriatic line to the northwest–southeast striking PA–AD plate boundary. This change of the plate tectonic regime in the Pannonian domain may coincide with the tectonic transition from extension to compression in this area during Pliocene and Quaternary (e.g., Bada et al., 2007; Fodor et al., 2005).

A kinematic model of the active tectonics around the triple junction was derived by Brückl et al. (2010). This model assumes sinistral strike-slip along the EU–PA boundary and stability of the AD–EU–PA triple junction. The PA extrudes at 1 mm year^{-1} to the east, and the convergence between the AD (especially the Adriatic foreland) and the EU amounts to 3 mm year^{-1} according to GPS data (Grenerczy and Kenyeres, 2006). The geodetic data also suggest a compressional zone south of the EU–AD plate boundary. These assumptions and data determine the kinematic model at and near the triple junction. South-to-north-oriented convergence is partitioned into 80% compression of AD and 20% subduction of EU under AD. The relative plate movement of PA versus AD changes from spreading at the triple junction (compensated by west–east-oriented extension of PA) to pure dextral strike-slip and transpression to the south of the PA–AD plate boundary. This kinematic model fits the geodetic data and explains the spatial distribution of seismicity and focal mechanisms.

1.17.6 Summary

The POLONAISE'97, CELEBRATION 2000, ALP 2002, and SUDETES 2003 seismic experiments in Central Europe provide unprecedented seismic coverage of lithospheric structure over a large area (**Figure 17**). The analysis of the resulting huge data set provided by this massive international cooperative effort is far from complete. However, we have learned a great deal about the complex structure along the TESZ and eastern Alpine regions in particular. In the TESZ area, we have delineated a deep basin, the lower portion of which is sediments and volcanic associated with the rifted margin of Baltica. In addition, several crustal blocks exist along this margin but appear to mostly be of Baltican origin with Variscan terranes lying outboard to the southwest. The Pannonian/Carpathian/TESZ region displays a complex structure with a surprising northward dip in the deep crust and uppermost mantle and southward dips in the upper crust. This geometry may well reflect multiple phases of subduction as well as collision-related features.

In the eastern Alpine region, 2-D interactive modeling by ray tracing and the application of 3-D stacking techniques substantially improved our knowledge of the lithospheric structure in this area. We have identified three main tectonic blocks: Europe (EU), Adria (AD), and the Pannonian domain (PA). These blocks meet at a triple junction near the southeastern termination of the Tauern window. The Alp01 and Alp02 profiles resolved different crustal structures related to collisional tectonics west of the triple junction and escape or extrusion east of it. Finally, we have formulated a tectonic model of evolution of the eastern Alpine region over the past 40 My that is consistent with a variety of geologic and geophysical data including velocity models of the upper mantle derived from teleseismic data.

1.18.1 Definitions of the Lithosphere and Asthenosphere

Earth's lithosphere, the 'strong' outermost layer of Earth often equated with tectonic plates, and the underlying 'weak' asthenosphere have multiple definitions. Kinematically, the lithosphere is often thought of as the layer of crust and mantle that translates coherently with plate motions, creating shear within the asthenosphere (**Figure 1**). Rheologically, the lithosphere is considered to have high viscosity relative to the asthenosphere. In terms of temperature, the lithosphere is the cold boundary layer through which Earth loses heat and cools, and heat transport in the lithosphere is typically equated with conduction, as opposed to convection at greater depths in the mantle. Compositional definitions also exist. The crust, comprising the upper lithosphere, is characterized by compositions that are more silica-rich than the mantle (e.g., **Chapter 1.13**), but in many regions, if not globally, the mantle lithosphere is also thought to be compositionally distinct from the asthenosphere and the deeper upper mantle. Possibilities include bulk compositions for the mantle lithosphere that are depleted and/or dehydrated relative to the asthenosphere because of melt extraction, as has been proposed for the oceanic lithosphere (e.g., Hirth and Kohlstedt, 1996; Karato and Jung, 1998) and corroborated in the subcratonic lithosphere by xenolith samples (e.g., Boyd, 1989; Jordan, 1978; Lee et al., 2011). It has also been proposed that asthenospheric viscosities are especially low owing to the presence of a small amount of partial melt (e.g., Anderson and Sammis, 1970; Hirschmann, 2010; Mierdel et al., 2007).

An ongoing challenge is to relate the physical and chemical properties inherent in these definitions of the lithosphere and asthenosphere to observable quantities that can be directly constrained by geophysical data. This chapter focuses on seismological measures of the properties of the lithosphere and asthenosphere, that is, how these layers are expressed in seismic wave velocities, including anisotropy, and attenuation. However, much can also be learned from lithospheric and asthenospheric conductivity models based on magnetotelluric studies (e.g., Baba et al., 2006; Eaton et al., 2009; Evans et al., 2011; Hirth et al., 2000; Naif et al., 2013), density constraints provided by geoid and gravity data, and geotherm estimates from heat flow data, particularly when these geophysical approaches are combined with xenolith-based geotherms and other geochemical and petrological information (see Artemieva (2011) and Lee et al. (2011) for excellent reviews).

1.18.2 Origins of the Seismological Lithosphere–Asthenosphere Boundary

Much has been learned about how seismic velocities and attenuation vary as a function of temperature, pressure, mineralogy, volatile content, grain size, and deformation-induced fabric, but the field has not yet progressed to the point where mantle composition and physical state can be unambiguously mapped to seismic properties. Helpful reviews can be found in **Chapter 1.26**, Karato (2003), Cooper (2003), Hacker and Abers (2004), Wiens et al. (2008), Karato et al. (2008), and Kohlstedt and Holtzman (2009). Nonetheless, a few general conclusions may be drawn when interpreting differences in seismic properties between the mantle lithosphere and asthenosphere.

Mantle seismic velocity will decrease (and attenuation will increase) as the temperature rises from the lithosphere into the asthenosphere; if temperature and pressure are the only variables that change, the resulting velocity and attenuation gradients will be gradual in depth (**Figure 2**). For example, in numerical models of mantle convection, lithosphere–asthenosphere temperature gradients typically occur over depth intervals of at least 50–70 km (e.g., Billen, 2008; Cooper et al., 2004; King and Ritsema, 2000; Korenaga and Jordan, 2002; Zaranek, 2005) (**Figure 1**) and create velocity and attenuation gradients over comparable depth ranges, as would models for simple conductive cooling of the oceanic lithosphere (e.g., Faul and Jackson, 2005; Rychert et al., 2012b;

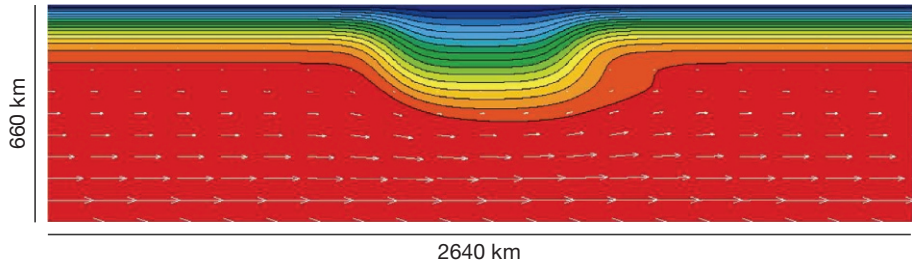

Figure 1 A depth profile of a numerical model in which the lithosphere corresponds to a high-viscosity layer that translates coherently over a lower viscosity asthenosphere. The model was calculated with a 2D hybrid finite difference–finite element approach and assumes an infinite Prandtl number, Boussinesq fluid. Viscosity is temperature dependent, and in the initial model, the lithosphere is assigned a viscosity of 10^{22} Pa s, whereas the reference viscosity in the asthenosphere is 10^{21} Pa s at 1350 °C; initial lithospheric thicknesses are 200 km in the middle and 100 km to the sides. Flow (indicated by white velocity vectors) is driven by a 6 cm per year velocity applied to the bottom boundary of the model, and this model has evolved over 100 My. Blue to red shading indicates increasing temperature (from 0 to 1350 °C), and temperature gradients at the base of the lithosphere occur over >50 km in depth. The fluid is cooled from above, the top boundary is held at a fixed temperature of 0 °C, and the heat flux is set to zero at the bottom boundary. A no-slip boundary condition was applied on the upper model boundary; side conditions are no-stress. The temperature dependence of viscosity is described by a value of 15 for activation energy/((gas constant)(reference temperature)). Reproduced from Zaranek SE (2005) *Roles of Convection in the Evolution of Planetary Interiors and Terrestrial Lithospheres*. PhD Thesis, Brown University, Providence, RI.

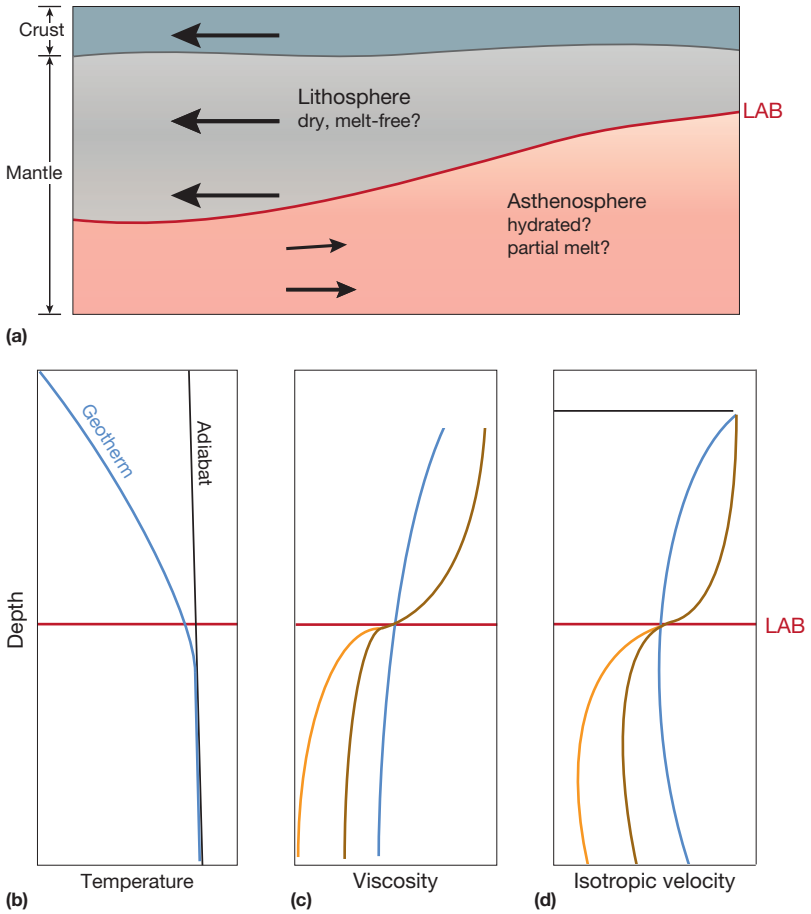

Figure 2 Schematic models of lithosphere–asthenosphere boundary (LAB) properties. (a) Depth profile through the lithosphere and asthenosphere. Arrows show the motion of a coherent lithospheric layer over a deforming asthenosphere. (b) Temperature as a function of depth. In the absence of other factors, the lithosphere would correspond to the cold thermal boundary layer represented by sub-adiabatic temperatures. (c) Mantle viscosity for three cases. Blue: the geotherm in (b). Brown: the geotherm combined with a compositional difference at the LAB (dry, depleted lithosphere over hydrated, fertile asthenosphere). Orange: the latter case plus partial melt in the asthenosphere. (d) Isotropic shear velocity corresponding to the three cases in (c). The black line schematically illustrates the velocity increase from the crust to the mantle. Vertical variations in composition and/or melt are capable of producing more localized gradients in viscosity and velocity than are possible with purely thermal models. Reproduced from Fischer KM, Ford HA, Abt DL, and Rychert CA (2010) The lithosphere–asthenosphere boundary. *Annual Review of Earth and Planetary Sciences* 38: 551–575, http://dx.doi.org/10.1146/annurev-earth-040809-152438, with permission of Annual Reviews, Inc.

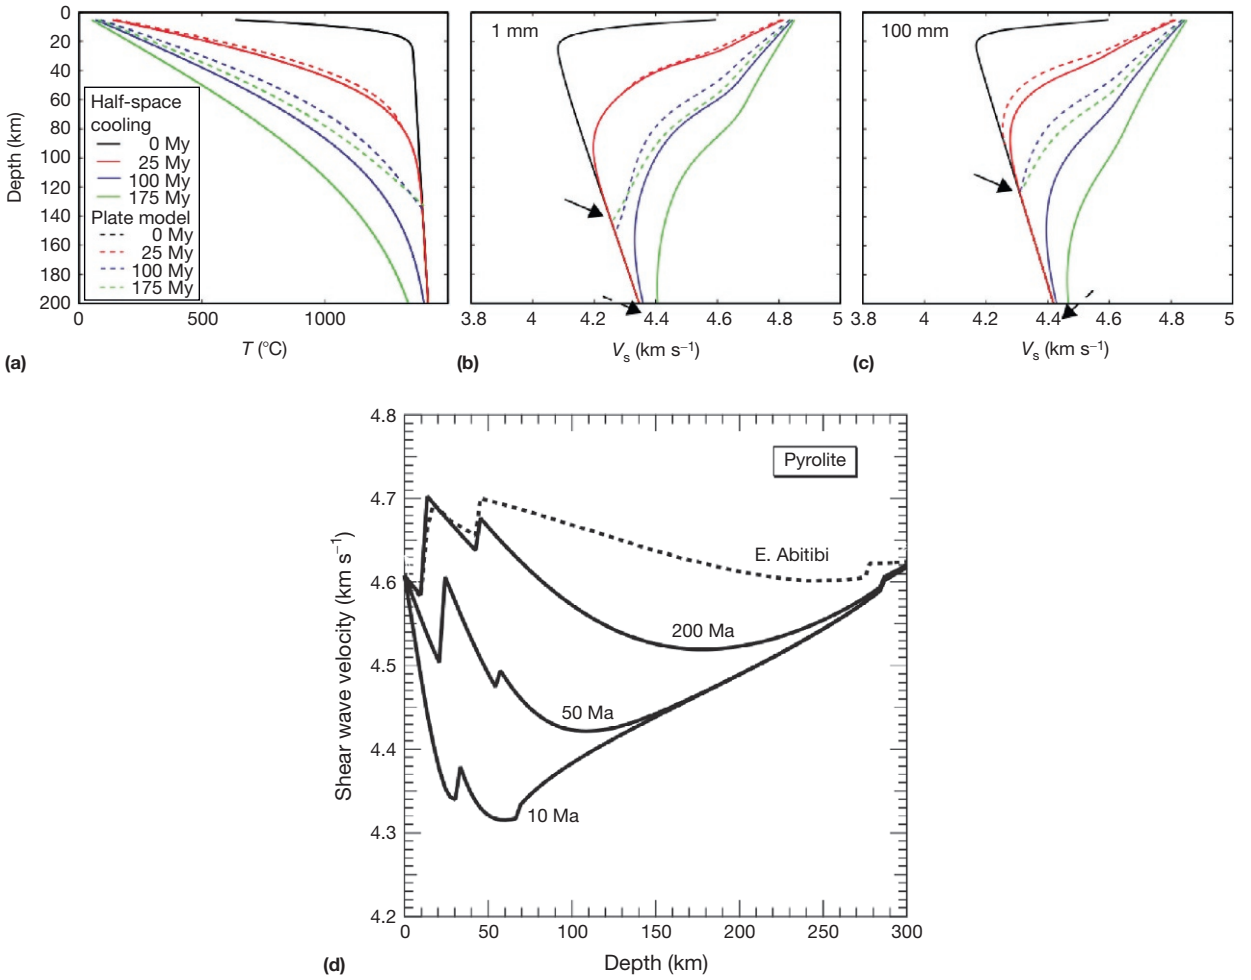

Figure 3 Models for the temperature dependence of shear-wave velocity. (a) Geotherms predicted for a half-space cooling model (solid) and a plate cooling model (dashed) for seafloor ages of 0 My (black), 25 My (red), 100 My (blue), and 175 My (green). Predicted seismic velocities using the temperature to velocity scaling of Jackson and Faul (2010) for mantle grain sizes of 1 mm (b) and 100 mm (c). Seismic wave frequency at each depth is assumed to follow the relationship of dominant period and peak depth sensitivity for fundamental mode Rayleigh waves. Arrows indicate depths at which predicted seismic velocities are the same for old (175 My) as well as young (25 My) oceanic lithosphere for both plate (solid) and half-space (dashed) cooling models; dashed arrows indicate a depth below the limits of the axes. (d) Shear-wave velocities predicted for oceanic geotherms of variable age (solid lines) and for a continental geotherm (dashed line). Reproduced from Stixrude L and Lithgow-Bertelloni C (2005) Mineralogy and elasticity of the oceanic upper mantle: Origin of the low-velocity zone. *Journal of Geophysical Research* 110, B03204, http://dx.doi.org/10.1029/2004jb002965, Copyright 2005 by the American Geophysical Union, with permission of John Wiley & Sons.

Stixrude and Lithgow-Bertelloni, 2005) (**Figure 3**). Sharper velocity gradients caused solely by temperature may be produced in regions of focused upwelling, but these will occur only in certain parts of some tectonic environments. Thus, in general, velocity and attenuation gradients that are localized over less than 40 km in depth likely indicate other factors in addition to temperature.

Mantle composition could produce significant gradients over smaller length scales. If the compositional variation is due to depletion by melt extraction, however, the magnitude of the resulting velocity changes is likely to be relatively small. Estimates of shear velocity change caused by reasonable ranges of Mg# vary from ~2.5% (Lee, 2003) to <1% (Schutt and Lesher, 2006). The effect of major element chemistry on upper mantle attenuation is thought to be negligible (Karato, 2003). Water, in the form of point defects in olivine, has the potential to produce larger changes in both shear velocity and attenuation (Hirschmann and Kohlstedt, 2012; Karato, 2003, 2012; Karato and Jung, 1998) although direct experimental evidence is only starting to emerge (Aizawa et al., 2008). Water will diffuse over time, but the length scales of diffusion are sufficiently small (<4 km over ~150 My; Hirth and Kohlstedt, 1996) for hydration variations to produce sharp gradients in seismic properties over Phanerozoic time-scales, with more gradual gradients possible over Proterozoic to Archean time-scales.

The presence of partial melt in the mantle has the potential to reduce seismic velocity and attenuation, although the magnitude of this effect depends strongly on the distribution of

melt at grain boundaries, including its shape/aspect ratio, and on the frequency of the seismic phases, and the mechanisms and magnitude of melt effects are still debated (e.g., Karato, 2012; Kawakatsu et al., 2009; Kohlstedt and Holtzman, 2009; Takei and Holtzman, 2009). If significant melt collects at the top of the asthenosphere, because the base of the lithosphere is relatively impermeable and/or corresponds to the melt solidus (e.g., Hirschmann, 2010; Till et al., 2010), the resulting reduction in asthenospheric velocity, shear velocity in particular, could be large and localized in depth. Conversely, if melt is able to permeate the deep lithosphere, its effects could counteract the otherwise high lithospheric velocities resulting from a dehydrated and depleted composition and colder temperatures, thus creating a gradual or negligible lithosphere–asthenosphere velocity gradient.

Other factors that could contribute to velocity and attenuation gradients between lithosphere and asthenosphere include the grain size of mantle minerals (e.g., Behn et al., 2009; Faul and Jackson, 2005), and frequency dependence in the grain-scale deformation mechanism, such as the peak in anelastic relaxation caused by elastically accommodated grain boundary sliding (Karato, 2012).

Finally, shearing between the lithosphere and asthenosphere will produce lattice-preferred orientation of the anisotropic mantle minerals olivine and orthopyroxene if deformation occurs in the dislocation creep regime (e.g., Karato et al., 2008). Vertical variations in the orientation and strength of seismic anisotropy, therefore, provide another means of estimating the depth and vertical localization of the lithosphere–asthenosphere boundary (LAB).

1.18.3 Imaging the Seismological LAB

This chapter focuses on the seismologically defined LAB, how its properties vary between tectonic settings (oceans, young continents, and cratons), and how they constrain the origins of this fundamental mantle transition. LAB properties of particular interest include the total thickness of the high-velocity lithosphere, the presence or absence of an underlying low-velocity asthenosphere, and differences in seismic velocities (including radial and azimuthal anisotropy), layering/discontinuities, and attenuation between the mantle lithosphere and asthenosphere.

The constraints on three-dimensional structure throughout the volume of the upper mantle provided by tomographic imaging (**Chapter 1.11**) are essential for understanding the LAB. Tomography that involves surface waves is especially useful since it typically provides better vertical resolution within the upper 200 km of the mantle compared to teleseismic body-wave tomography (e.g., Priestley and Tilmann, 2009). Variations in lithospheric thickness appear prominently in both global (**Figures 4** and **5**) and regional models. In map-view (**Figure 4**), the thicker lithosphere found beneath stable cratonic regions is indicated by high velocity and low attenuation persisting to depths greater than 100 km, whereas low velocity and high attenuation at 100 km depth beneath young seafloor signify that the lithosphere must be very thin in these regions.

Vertical variations in absolute velocity highlight velocity gradients across the LAB. For example, clustering analysis of vertical shear-velocity profiles in a recent global model obtained by inverting long-period waveforms reveals that the velocity profiles of young, middle-aged, and old oceanic upper mantle are distinct, as are those of cratons and more recently deformed continental regions (Lekic and Romanowicz, 2011a,b). In these models, the LAB velocity gradient can be viewed as the transition from high-velocity lithosphere to low-velocity asthenosphere, a variation that occurs from <50 to 100 km depth in the youngest oceans and from ~180 to ~250 km beneath cratons. However, models based on surface waves and long-period waveforms alone are not able to distinguish between LAB velocity gradients as gradual as those in the models in **Figure 5** and gradients that are much more localized in depth. This difficulty in distinguishing between sharp and gradual LAB gradients has been quantitatively estimated in fundamental mode Rayleigh wave inversions (Bartzsch et al., 2011; Eaton et al., 2009). While the incorporation of surface wave overtones (e.g., **Figure 5**) will typically improve vertical resolution, these inversions will still have difficulty in differentiating between gradients over ~50 km and those over smaller

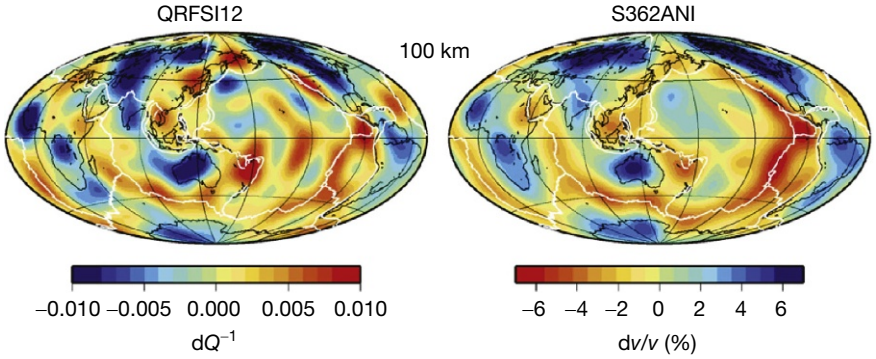

Figure 4 Models of global shear attenuation (left) and shear velocity (right) shown at a depth of 100 km illustrate differences between cratonic regions where the lithosphere is characterized by thick layers with high velocity and low attenuation, and regions with thinner lithosphere. The attenuation model (Dalton et al., 2008) is plotted as its deviation from the globally averaged attenuation value at 100 km. Isotropic velocities from the radially anisotropic shear-velocity model of Kustowski et al. (2008) are shown expanded in spherical harmonics up to degree 12. Reprinted from Dalton CA, Ekström G, and Dziewonski AM (2009) Global seismological shear velocity and attenuation: A comparison with experimental observations. *Earth and Planetary Science Letters* 284: 65–75, Copyright 2009, with permission from Elsevier.

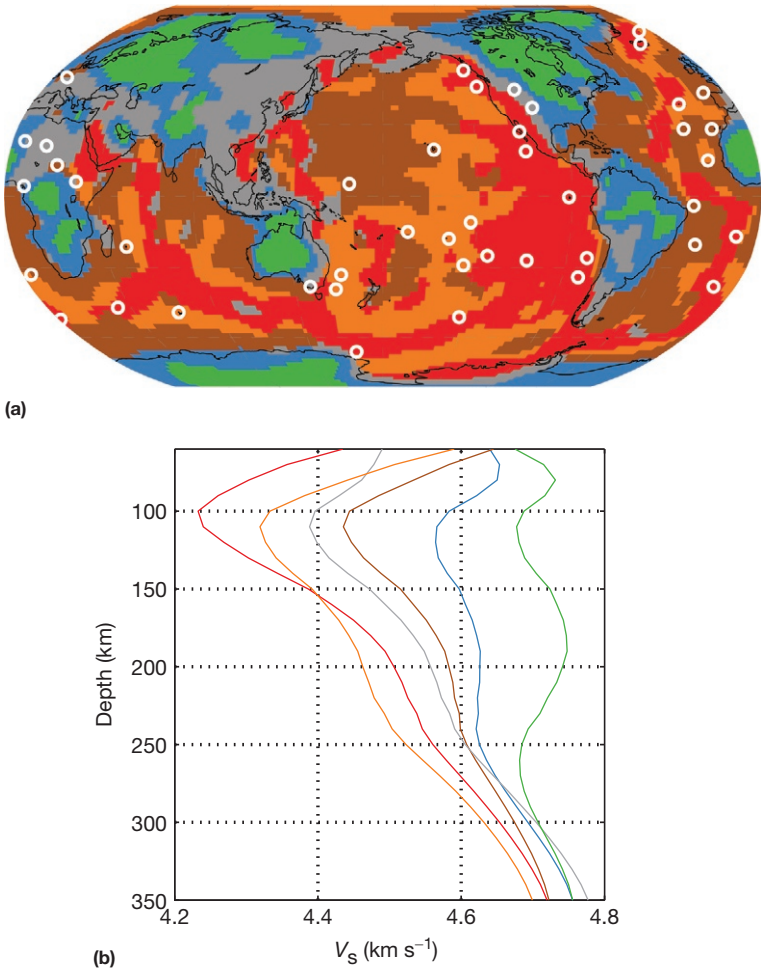

Figure 5 A global model of absolute shear-wave velocity that illustrates thicker, high-velocity lithosphere beneath cratonic regions and thinner lithosphere beneath younger continental regions and oceans. A decrease in absolute velocity with depth into a layer interpretable as the asthenosphere is present globally, and asthenospheric velocities are lowest beneath young oceans. (a) Geographic extents of six regions defined by *k*-means clustering as having similar absolute shear-velocity profiles in the model of Lekic and Romanowicz (2011a) that includes radial anisotropy. The clusters roughly delineate regions with young (red), middle-aged (orange), and old (brown) oceanic crust, more recently tectonized continental crust (gray), and cratons (green). (b) Average isotropic shear-velocity profiles corresponding to the six clusters. Reprinted from Lekic V and Romanowicz B (2011) Tectonic regionalization without a priori information: A cluster analysis of upper mantle tomography. *Earth and Planetary Science Letters* 308: 151–160, Copyright 2011, with permission from Elsevier.

depth ranges. In addition, the magnitude of the velocity drop at the LAB exhibits dependence on the starting model used in the tomographic inversion (e.g., Romanowicz, 2009) and varies considerably between different studies (Bedle and van der Lee, 2009; Kustowski et al., 2008; Lekic and Romanowicz, 2011a,b; Nettles and Dziewoński, 2008; Ritsema et al., 2011; Yuan et al., 2011).

In addition to gradients in isotropic velocity, vertical variations in either radial or azimuthal velocity anisotropy provide another means of defining the LAB. (See **Chapter 1.10** for discussion of wave propagation in anisotropic media.) For example, shear in the asthenosphere in the dislocation creep regime could create azimuthal anisotropy with a distinct orientation or strength relative to anisotropy in the mantle lithosphere. If azimuthal anisotropy generated by roughly horizontal shear is averaged over back-azimuth, it appears as radial anisotropy with a slow vertical axis and, thus, vertical variations in radial anisotropy might also be expected at the LAB. Changes in anisotropy at the LAB have been explored with inversions involving surface waves and long-period waveforms at both regional (e.g., Chen et al., 2007; Darbyshire and Lebedev, 2009; Debayle and Kennett, 2000; Deschamps et al., 2008; Ekström and Dziewonski, 1998; Gaherty, 2004; Gaherty and Jordan, 1995; Gaherty et al., 1996, 1999; Li et al., 2003, 2005; Lin et al., 2011; Maggi et al., 2006; Marone and Romanowicz, 2007; Nishimura and Forsyth, 1988, 1989; Simons et al., 2002; Yuan and Romanowicz, 2010a,b; Yuan et al., 2011) and global scales (e.g., Beucler and Montagner, 2006; Debayle et al., 2005; Ekström, 2000, 2011; Gung et al., 2003; Montagner and Tanimoto, 1990; Nettles and Dziewoński, 2008; Plomerová et al., 2002; Trampert and Woodhouse, 2003). Incorporating shear-wave splitting in teleseismic phases such as SKS into surface wave tomography adds constraints on azimuthal anisotropy, particularly at greater

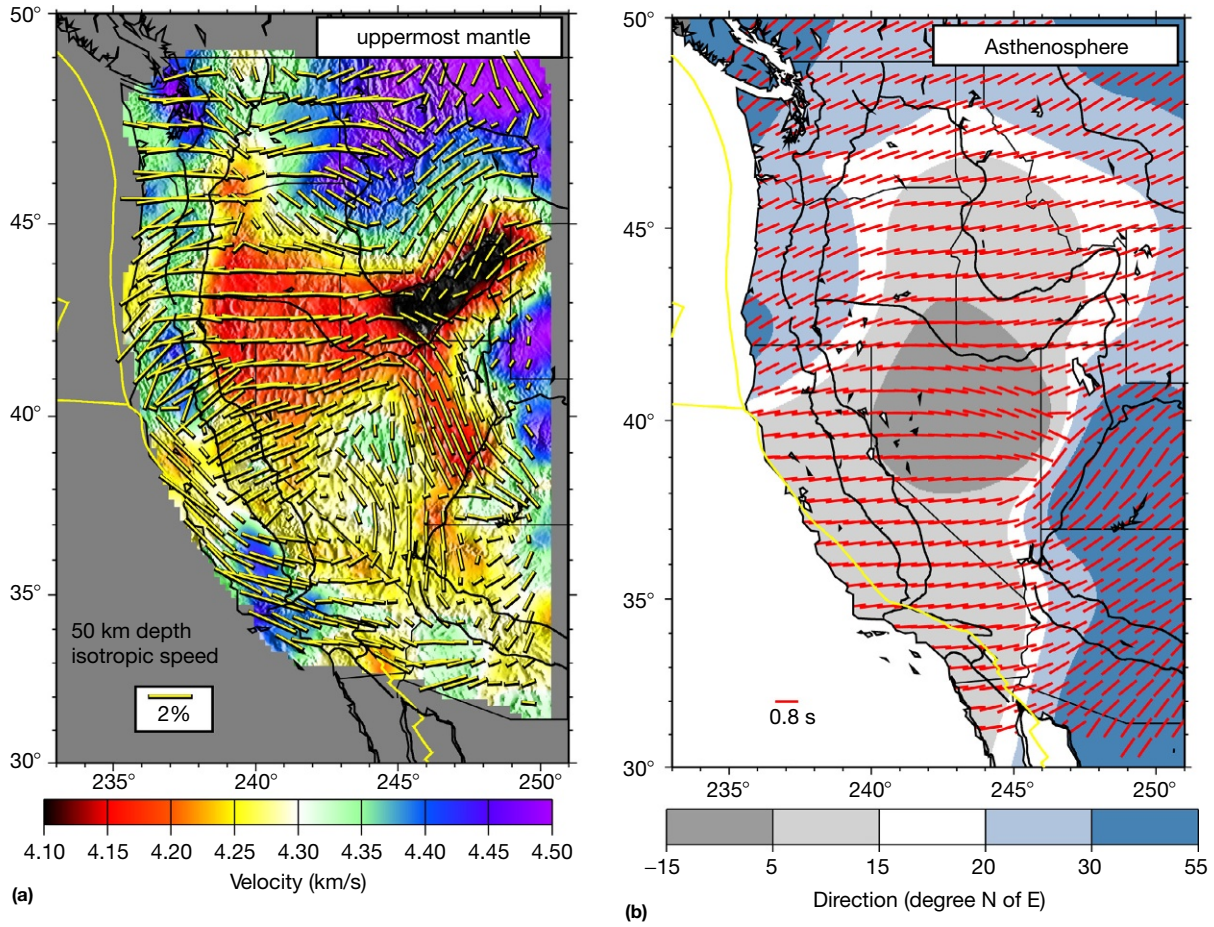

Figure 6 A shear-velocity model for the western United States that illustrates variations in azimuthal anisotropy between the shallow mantle lithosphere and the asthenosphere. (a) Isotropic velocity (background color) and azimuthal anisotropy at a depth of 50 km beneath the western United States. Yellow bars indicate the fast axis and amplitude of azimuthal anisotropy. (b) The direction of the fast axis of azimuthal anisotropy in the asthenosphere (background color and red bar orientation) and the amplitude of anisotropy measured as its equivalent SKS phase splitting time (red bar length). Reprinted from Lin FC, Ritzwoller MH, Yang Y, Moschetti MP, and Fouch MJ (2011) Complex and variable crustal and uppermost mantle seismic anisotropy in the western United States. *Nature Geoscience* 4: 55–61, Copyright 2011, by permission from Macmillan Publishers Ltd.

depths where surface waves lose sensitivity (Gaherty, 2004; Li et al., 2003; Lin et al., 2011; Marone and Romanowicz, 2007; Yuan and Romanowicz, 2010a,b; Yuan et al., 2011) (**Figure 6**). However, vertical resolution of gradients in anisotropy at the LAB using these methods is on the order of 50 km or more in depth.

Complementary resolution of LAB depths and velocity gradients is provided by phases whose paths dive through the LAB region, including multiple-bounce S waves (Tan and Helmberger, 2007) and regional P and SH waveforms (Chu et al., 2012a,b, in press; Grand and Helmberger, 1984) (**Figure 7**). However, in models based on these phases, tradeoffs exist between the magnitude of the LAB velocity drop and the depth range over which it is distributed, creating uncertainty in the LAB velocity gradient. For example, regional P waveforms that indicate an LAB gradient centered at ~180 km can be fit almost equally well by a larger velocity drop over ~30 km in depth and a smaller velocity drop over ~60 km in depth (Chu et al., 2012a).

A more precise vertical resolution of LAB velocity gradients may be obtained from teleseismic phases that convert or reflect at the LAB (e.g., **Chapter 1.09**). Examples include ScS reverberations (Bagley and Revenaugh, 2008; Revenaugh and Jordan, 1991), SS precursors (Rychert and Shearer, 2011; Rychert et al., 2012b; Schmerr, 2012), and Sp and Ps phases (Figure) (reviews may be found in Eaton et al., 2009; Fischer et al., 2010; Kind et al., 2012; Rychert et al., 2010). The presence of a significant Sp arrival typically indicates a shear-velocity gradient that is localized over ~30 km or less, assuming that the velocity drop is ~8% or less (Ford et al., 2010; Rychert et al., 2007, 2010). The shorter periods in Ps phases provide an even sharper vertical resolution, for example, showing that vertical gradients over less than 15 km are required (Rychert et al., 2005, 2007). Adding reflected and converted phases to inversions of surface waves and long-period waveforms adds significantly to vertical resolution of LAB velocity gradients (Bodin et al., 2014; Gaherty et al., 1996, 1999). For example, Gaherty et al. (1996) concluded that the Pacific LAB corresponded to a shallow (~70 km depth) vertical gradient over 30 km or less based on a joint inversion of long-period waveforms and ScS reverberations. In contrast, Bodin et al. (2014) used a joint inversion of Sp receiver functions and surface wave

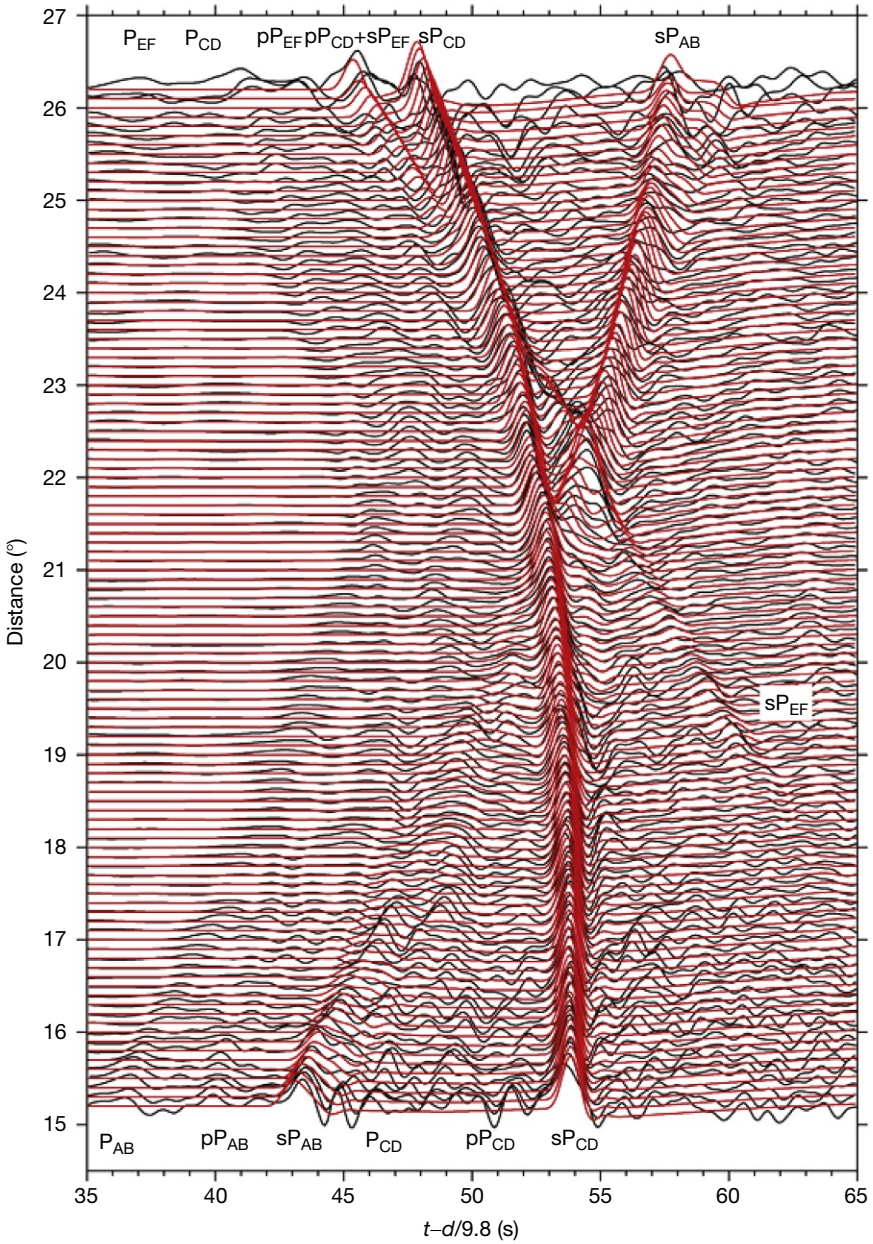

Figure 7 Regional waveforms indicate that a negative velocity gradient centered at ~180 km depth (interpretable as the LAB) exists beneath a portion of cratonic North America. Stacked waveforms from an earthquake in Quebec recorded by stations of the EarthScope Transportable Array are shown in red and synthetic waveforms for a one-dimensional model of P-wave velocity of the cratonic upper mantle are shown in black. In the model, a low-velocity zone starts at depths of ~165 km. This feature is reflected in the sP_{AB} branch, which is clear at distances of less than 18°, but loses amplitude at slightly greater distances because of the low-velocity zone. sP_{AB} amplitudes increase beyond 22° where phase raypaths turn below the low-velocity zone. Reproduced from Chu R, Schmandt B, and Helmberger DV (2012a) Upper mantle P velocity structure beneath the Midwestern United States derived from triplicated waveforms. *Geochemistry*, *Geophysics*, *Geosystems* 13, Q0AK04, http://dx.doi.org/10.1029/2011GC003818, Copyright 2012 by the American Geophysical Union, with permission of John Wiley & Sons.

dispersion to demonstrate that the LAB beneath Hyderabad, India, is both deep and gradual, extending from depths of 150–200 km. Resolution of azimuthally anisotropic shear-velocity gradients with reflected and converted phases such as SS precursors (Rychert et al., 2012b) and Sp receiver functions (Ford, 2013) is also being explored.

Active source reflection and refraction data have also imaged velocity gradients and/or reflectors inferred to be the transition from a shallower high velocity layer to a deeper low-velocity zone (MONA LISA Working Group, 1997; Morozova et al., 1999; Pavlenkova et al., 2002; Perchuc and Thybo, 1996; Ryberg et al., 1996; Steer et al., 1998a,b; Thybo, 2006; Thybo and Perchuc, 1997); in order to be visible at the high frequencies in active source data, these features must be highly localized in depth. The 8° discontinuity (a delay in the first arriving phase at a distance of ~8°) observed in many

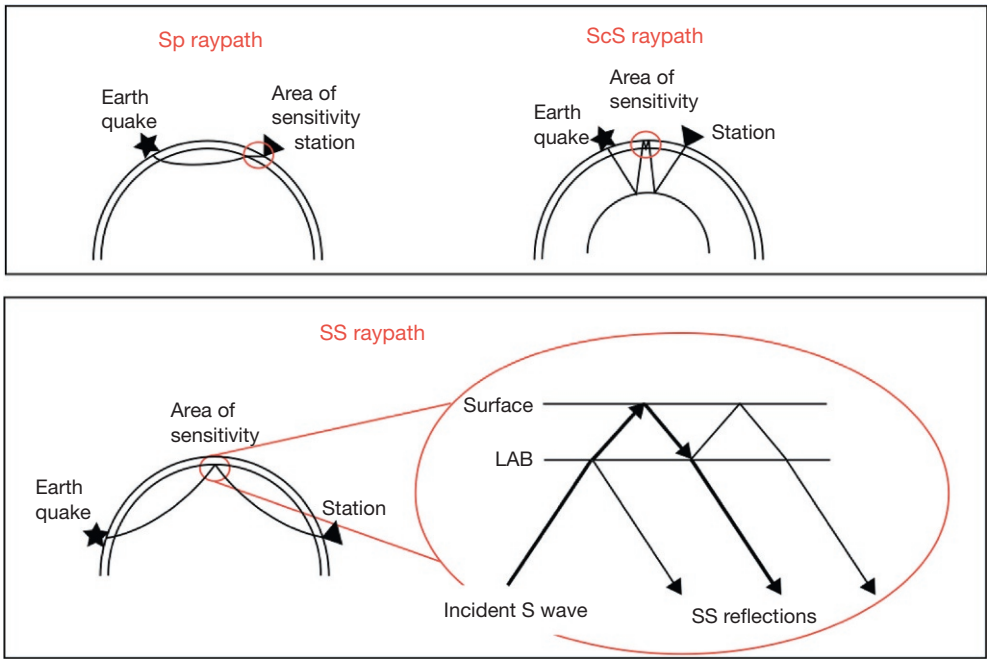

Figure 8 Schematic diagram of raypaths for reflected and convert phases used to image the LAB. Red circles show the regions where the particular paths shown are sensitive to LAB structure. Reverberations from ScS multiples will reflect at the discontinuity at other points along the path, and this family of phases results in path-averaged estimates of discontinuity properties. Multiple-bounce S waveforms look similar to the SS, but with additional bounces at Earth's surface between source and receiver (e.g., Tan and Helmberger, 2007). Reproduced from Rychert CA, Schmerr N, and Harmon N (2012) The Pacific lithosphere–asthenosphere boundary: Seismic imaging and anisotropic constraints from SS waveforms. *Geochemistry, Geophysics, Geosystems* 13, Q0AK10, http://dx.doi.org/10.1029/2012GC004194, Copyright 2012 by the American Geophysical Union, with permission of John Wiley & Sons.

long-range seismic profiles has been interpreted to represent a widespread low-velocity zone whose top lies at a depth of ~100 km (e.g., Nielsen et al., 2002; Thybo, 2006; Thybo and Perchuc, 1997). In younger continental regions with thinner lithosphere, the 8° discontinuity could correspond to the LAB. However, in cratonic regions where fast velocities indicative of the lithosphere extend to depths of 150 km or more, the low-velocity zone associated with the 8° discontinuity would lie within the lithosphere. An 8° discontinuity has also been observed in passive source regional P waveforms (Chu et al., 2012a).

1.18.4 The Seismological LAB Beneath Oceans

Given its relatively simple kinematic and thermal history, the oceanic lithosphere provides a particularly useful setting in which to test competing models for the factors that control LAB velocity gradients. A number of hypotheses have been proposed to explain the age-dependent deepening of the seafloor, which is often described as following the prediction of conductive cooling of the mantle with an asymptotic plate thickness (Parsons and Sclater, 1977; Stein and Stein, 1992). Hypotheses include conductive cooling plus small-scale convection below the lithosphere (e.g., Eberle and Forsyth, 1995; Parsons and McKenzie, 1978; Yuen and Fleitout, 1985), large-scale mantle plumes (e.g., Davies, 1988), asthenospheric flow fed by mantle plumes (Phipps Morgan et al., 1995), and overall readjustment of the oceanic upper thermal boundary layer in response to underlying mantle convection (Adam and Vidal, 2010). All of these hypotheses predict some cooling of the oceanic lithosphere with crustal age, except for Adam and Vidal (2010) who prefer a relationship of seafloor depth with distance along mantle flow lines.

If the properties of the oceanic lithosphere are governed by temperature alone and temperature is controlled by one of the age-dependent hypotheses, the LAB would deepen with crustal age. For all hypotheses, the LAB velocity gradient would be distributed over many tens of kilometers in depth, particularly in regions of old oceanic lithosphere (e.g., Faul and Jackson, 2005; Rychert et al., 2012b; Stixrude and Lithgow-Bertelloni, 2005) (**Figure 3**). If the base of the oceanic lithosphere corresponds to the mantle solidus, for example, the solidus of peridotite containing small amounts of water and CO_2 (Hirschmann, 2010) (**Figure 9**), the depth of the LAB would increase more slowly with crustal age (assuming age-dependent cooling) and the presence of melt in the asthenosphere could create a larger drop in velocity at the LAB that is more localized in depth (possibly a few kilometers or less). If, instead, the oceanic lithosphere corresponds to a layer of dry, chemically depleted peridotite (e.g., Hirth and Kohlstedt, 1996), once created its thickness would not change with crustal age, and the LAB velocity gradient could occur over a few kilometers, although the magnitude of the velocity drop would be smaller than the maximum velocity drops hypothesized for melt, particularly at the base of old (>100 Ma) oceanic lithosphere (e.g., Karato and Jung, 1998; Kawakatsu et al., 2009). However, if the base of the dry depleted layer is

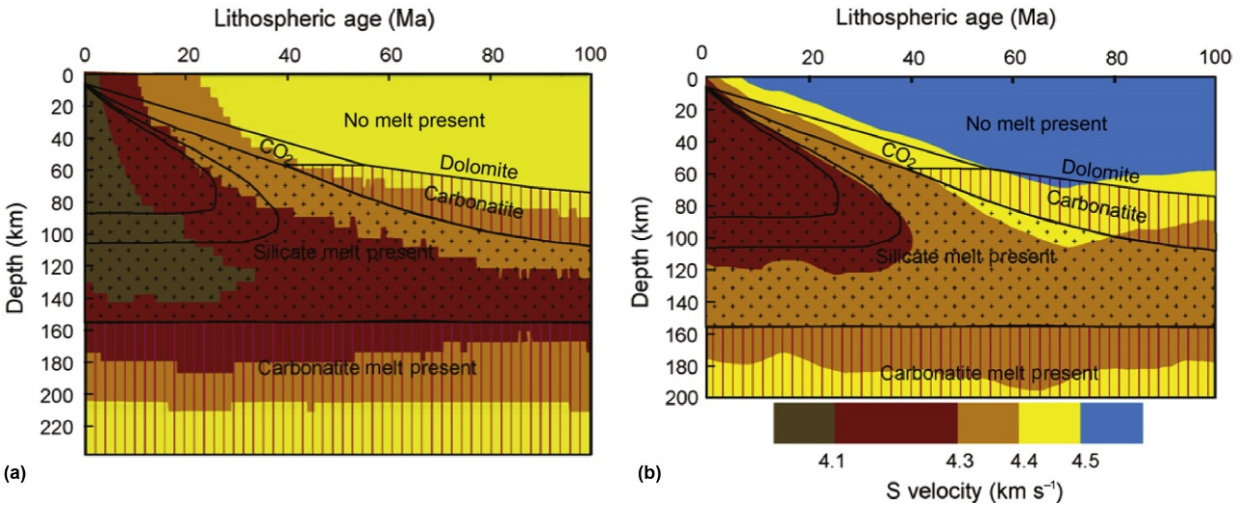

Figure 9 Diagram showing melt distribution in the oceanic upper mantle predicted for a mantle potential temperature of 1350 °C superimposed on average shear-velocity profiles for a given lithospheric age from the tomographic models of (a) Priestley and McKenzie (2006) (SV component velocities) and (b) Ritzwoller et al. (2004) (isotropic velocity in a model that includes radial anisotropy). Regions of silicate melt stability and greater calculated melt fractions, in general, correspond to lower shear velocities; this correlation is consistent with, but does not require, partial melt contributing to reduction of shear velocity. Reprinted from Hirschmann MM (2010) Partial melt in the oceanic low velocity zone. *Physics of the Earth and Planetary Interiors* 179: 60–71, Copyright 2010, with permission from Elsevier.

relatively impermeable to melt, melt could collect at the top of the asthenosphere, enhancing the drop in shear velocity. Vertical variations in olivine grain size can also contribute to increasing velocity gradients (Behn et al., 2009; Faul and Jackson, 2005) (**Figure 3(a)–3(c)**, from Rychert et al., 2012b). In addition, Karato (2012) proposed that the shear-velocity gradient at the oceanic LAB may be produced by anelastic relaxation from elastically accommodated grain boundary sliding, assuming a hydrated asthenosphere and a dry lithosphere.

The existence and degree of age dependence in the apparent thickness of a high-velocity lithospheric layer and the velocity gradient at the apparent seismological LAB are key constraints when testing different candidate processes for creating the oceanic lithosphere; the character of anisotropy in the lithosphere and asthenosphere adds insight into deformation in these layers. A synthesis of diverse seismological constraints on the oceanic lithosphere and asthenosphere reveals that different types of seismic waves are consistent with different types of structures, and no single process for generating the oceanic LAB explains all the observations.

1.18.4.1 Tomographic Studies

Surface waves and long-period waveforms show an increase in the thickness and maximum velocity of the high-velocity lithospheric layer as a function of crustal age (**Figures 5, 9**, and **10**) (e.g., Ekström, 2000; Lekic and Romanowicz, 2011a,b; Maggi et al., 2006; Nettles and Dziewoński, 2008; Nishimura and Forsyth, 1988, 1989; Priestley and McKenzie, 2006; Ritzwoller et al., 2004). In addition, the observed increase in the minimum asthenospheric velocity beneath older oceanic lithosphere (**Figures 5(b)** and **10**) is consistent with cooler temperatures (or less melt or water) in the asthenosphere. However, while these age-dependent patterns are pronounced, alternating high-velocity and low-velocity regions in the direction normal to absolute plate motion have also been documented, initially from Tonga to Hawaii (Katzman et al., 1998) but now globally (French et al., 2013), and these features suggest a pattern of secondary convection.

The oceanic asthenosphere is also the locus of particularly strong radial anisotropy with a slow vertical symmetry axis (**Figure 10**) (Ekström and Dziewonski, 1998; French et al., 2013; Kustowski et al., 2008; Lekic and Romanowicz, 2011a; Nettles and Dziewoński, 2008; Nishimura and Forsyth, 1989; Smith et al., 2004), except beneath mid-ocean ridges where, in some studies, the vertical symmetry axis is fast (Montagner, 2002; **Figure 7** in **Chapter 1.19**; French et al., 2013). These geometries of anisotropy are consistent with horizontal flow in the asthenosphere away from ridges but vertical flow directly beneath ridges. Azimuthal anisotropy in the oceanic asthenosphere, in general, manifests a fast horizontal symmetry axis that is roughly aligned in the direction of absolute plate motion, although geodynamic models that incorporate three-dimensional flow tend to fit observed azimuthal patterns better than simple absolute plate motion predictions; azimuthal anisotropy resolved in the oceanic lithosphere is more consistent with the direction of seafloor spreading frozen into the lithosphere at the ridge where it formed (Becker et al., 2007; Debayle et al., 2005; Ekström, 2011; Forsyth, 1975; Gaboret et al., 2003; Maggi et al., 2006; Nishimura and Forsyth, 1988, 1989; Smith et al., 2004; Tanimoto and Anderson, 1984). These constraints on anisotropy are consistent with the idea that the isotropically high-velocity oceanic lithosphere corresponds to a layer that is translating with little continued deformation, whereas the isotropically low-velocity asthenosphere has a significantly lower viscosity and accumulates strain and anisotropy because of ongoing mantle convection.

The age-dependent trends in the surface wave and long-period waveform tomography are consistent with an oceanic

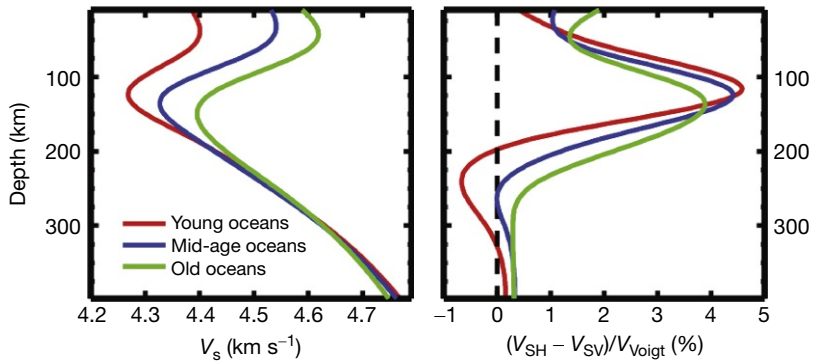

Figure 10 Average shear-wave velocity from surface wave tomography for oceanic regions with different plate ages, with (left) absolute isotropic velocities and (right) radial anisotropy. This model illustrates the presence of strong radial anisotropy in the oceanic asthenosphere, as well as increases in the thickness and maximum velocity of the high-velocity lithospheric layer and the minimum asthenospheric velocity as a function of crustal age. Reproduced from Nettles M and Dziewoński AM (2008) Radially anisotropic shear velocity structure of the upper mantle globally and beneath North America. *Journal of Geophysical Research* 113, http://dx.doi.org/10.1029/2006jb004819, Copyright 2008 by the American Geophysical Union, with permission of John Wiley & Sons.

lithosphere whose thickness is defined by cooling and whose LAB velocity gradient depends only on temperature and, hence, is distributed gradually in depth. The tomography models are also consistent with an LAB that corresponds to time-dependent deepening of the solidus (e.g., Hirschmann, 2010; **Figure 9**). Although they do not require an LAB velocity gradient that is localized in depth, as could be produced by partial melt in the asthenosphere versus a melt-free lithosphere, they also are not incompatible with one; moreover, gradients in melt could also be gradual. The age-dependent trends in the tomography models are not consistent with an oceanic lithosphere that is defined solely as a layer of dry, depleted peridotite, in the absence of cooling, since such a model would produce no age dependence to either the depth of the LAB or the velocity contrast between lithosphere and asthenosphere. However, the combination of cooling and a dry, depleted lithosphere over a more hydrated and fertile asthenosphere could potentially replicate the tomography, since greater cooling at older crustal ages could increase velocities in the mantle below the dehydration/depletion boundary, thus increasing the apparent thickness of a high-velocity layer. Cooling would also reduce the magnitude of the velocity drop at the dehydration/depletion boundary at older crustal ages by reducing the impact of water in olivine on attenuation and, therefore, on shear velocity (e.g., Karato and Jung, 1998).

1.18.4.2 Converted and Reflected Wave Studies

While surface wave and long-period waveform tomography is compatible with a broad range of models, creation of the oceanic LAB by thermal gradients alone is challenged by studies of reflected and converted seismic waves that document LAB velocity gradients that occur over 30 km or less. The degree of depth localization in the LAB velocity gradient varies with the type of seismic phase and its frequency content. In addition, while some reflected and converted phase studies are compatible with an increase in the apparent thickness of a high-velocity layer with crustal age, others are not, thus raising questions about whether either simple cooling or solidus-based models can universally explain oceanic lithospheric seismic properties. Fischer et al. (2010) and Rychert et al. (2012b) provide additional reviews (e.g., **Figure 11**).

Studies that show a lack of age dependence in the apparent thickness of the oceanic lithosphere include analyses of ScS reverberations (Bagley and Revenaugh, 2008; Revenaugh and Jordan, 1991), waveform inversion combined with ScS reverberations (Gaherty et al., 1996, 1999), modeling of multiple-bounce S phases (Tan and Helmberger, 2007), and Sp and Ps phases at stations on or near ocean islands.

Sp and Ps phases sample crust and mantle structure at the phase scattering point (**Figure 8**), and these points lie in a roughly annulus-shaped region around the station whose horizontal radius increases with increasing depth and phase ray parameter. Sp phases have the opposite polarity of Ps arrivals, but in receiver functions, Sp amplitudes are typically flipped to agree with the Ps convention. For the purposes of this chapter, 'negative' Sp phases will refer to what are, in fact, positive arrivals that correspond to a negative velocity gradient. Sp and Ps studies in the oceans have produced estimates of a significant drop in velocity at depths ranging from 40 to 140 km (Collins et al., 2002; Heit et al., 2007; Kumar et al., 2005a, 2007; Li et al., 2000, 2004; Rychert and Shearer, 2009; Vinnik et al., 2005; Wölbern et al., 2006), with a global Ps average of 70 ± 4 km (Rychert and Shearer, 2009), but these depth estimates have no apparent correlation with time since the lithosphere was generated at a mid-ocean ridge (Fischer et al., 2010; Rychert et al., 2010). However, since the ocean islands at which these measurements were made are associated with hotspot activity, the lithospheric thicknesses may be anomalous, complicating their interpretation.

ScS reverberations sample discontinuity structure at multiple reflection points along the path, resulting in a path-averaged estimate of discontinuity properties. Revenaugh and Jordan (1991) found a discontinuity corresponding to a drop in velocity at a depth of ~60 km beneath the ~100 Ma lithosphere between Tonga/Fiji and Hawaii, but data for this path were reexamined by Bagley and Revenaugh (2008) who concluded that a depth of ~108 km was more accurate. Bagley and

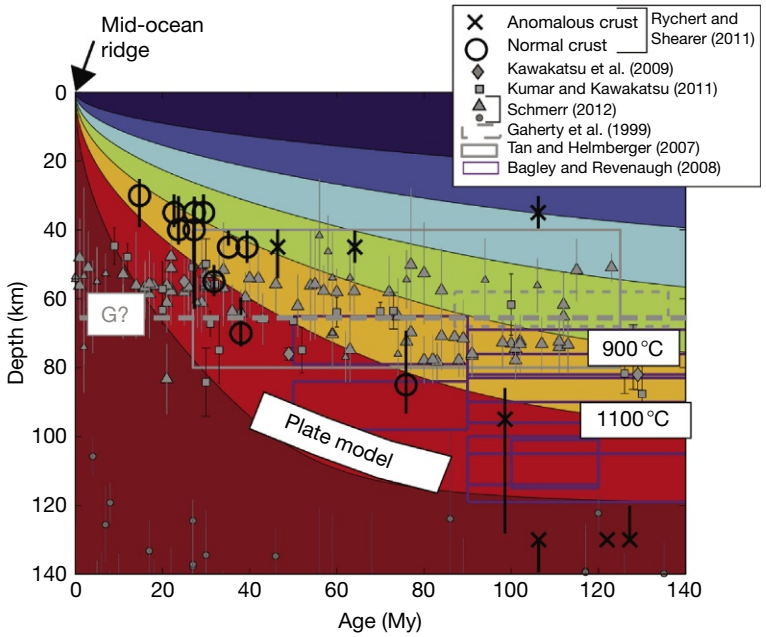

Figure 11 Observations of mantle discontinuity depths from the Pacific ocean compared to isotherms from a cooling plate model. Large black symbols correspond to long-period SS precursor results (Rychert and Shearer, 2011) where open circles correspond to normal seafloor and ×s are from areas with hotspot activity. Gray triangles are observations from short-period SS precursors; gray circles are also from short-period SS precursors, but they are a phase interpreted as the base of the low-velocity asthenosphere. Gray squares and diamonds are from Sp and Ps receiver functions (Kawakatsu et al., 2009; Kumar and Kawakatsu, 2011). Gray boxes show LAB depth from the shear-velocity models of Gaherty et al. (1996) (dashed) and Tan and Helmberger (2007). Purple boxes show discontinuity depths from ScS reverberations (Bagley and Revenaugh, 2008). Reproduced from Rychert CA, Schmerr N, and Harmon N (2012) The Pacific lithosphere–asthenosphere boundary: Seismic imaging and anisotropic constraints from SS waveforms. *Geochemistry, Geophysics, Geosystems* 13, Q0AK10, http://dx.doi.org/10.1029/2012GC004194, Copyright 2012 by the American Geophysical Union, with permission of John Wiley & Sons.

Revenaugh (2008) sampled a wide variety of corridors around the Pacific, and found negative discontinuities at depths ranging from 72 to 112 km, except for a path from Central America to Hawaii where no discontinuity was present in a comparable depth range. Overall, the apparent discontinuity depths are not well correlated with the range of crustal age on each corridor (as shown by the purple rectangles in **Figure 11**, which was compiled by Rychert et al. (2012b)) although the deepest discontinuity estimates do correspond to the oldest ages. These data imply large (>8%) velocity drops if they occur as step functions in depth and even greater velocity decreases as the depth range of the velocity gradient increases, leading Bagley and Revenaugh (2008) to the conclusion that the gradient must occur over 30 km or less.

Through a joint inversion of ScS reverberations with frequency-dependent travel-times from surface waves (Love and Rayleigh) and shear body waves (including S, sS, and multiple-bounce S phases), Gaherty et al. (1996) determined that a high-velocity layer with a thickness of 68 ± 4 km above a low-velocity layer best fit the corridor between Tonga/Fiji and Hawaii. Tan and Helmberger (2007) modeled multiple-bounce S phases on a corridor from Tonga/Fiji to southern California that spans a very wide range of crustal ages and found a high-velocity layer/low-velocity layer transition at a depth of 60 ± 20 km. Taken together, these two studies suggest a very uniform depth for the Pacific LAB and essentially no resolvable age dependence (solid and dashed gray rectangles in **Figure 11**). However, the ScS reverberations in the Gaherty et al. (1996) inversion were analyzed with the approach of Revenaugh and Jordan (1991), and when Bagley and Revenaugh (2008) reexamined the Revenaugh and Jordan (1991) ScS records with an updated instrument response, they obtained a deeper discontinuity estimate comparable to their preferred value of ~108 km depth for the Tonga/Fiji–Hawaii corridor. This point raises the question of whether the Gaherty et al. (1996) joint inversion approach might produce a deeper LAB with the Bagley and Revenaugh (2008) ScS constraints. However, while some trade-offs between the thickness and velocity of the high-velocity layer exist, the surface waves and other body wave phases used in the Gaherty et al. (1996) inversion would not be adequately fit by a high-velocity layer as thick as 100 km, although an ~75-km-thick layer would likely be possible (J. Gaherty, personal communication, 2013). However, even at 75 km, the Gaherty et al. (1999) fast layer thickness would still overlap the 60 ± 20 km estimate of Tan and Helmberger (2007).

Converted and reflected wave studies that argue for age dependence in lithospheric thickness include Sp and Ps phases that sample oceanic lithosphere near subduction zones (Kawakatsu et al., 2009; Kumar and Kawakatsu, 2011; Kumar et al., 2011) and SS precursors (Rychert and Shearer, 2011; Rychert et al., 2012b; Schmerr, 2012).

Sp and Ps receiver functions from the Pacific and Philippine Sea Plates near Japan (Kawakatsu et al., 2009; Kumar et al., 2011) and from around the rim of the Pacific (Kumar and Kawakatsu, 2011) (**Figure 12**) indicate the presence of a

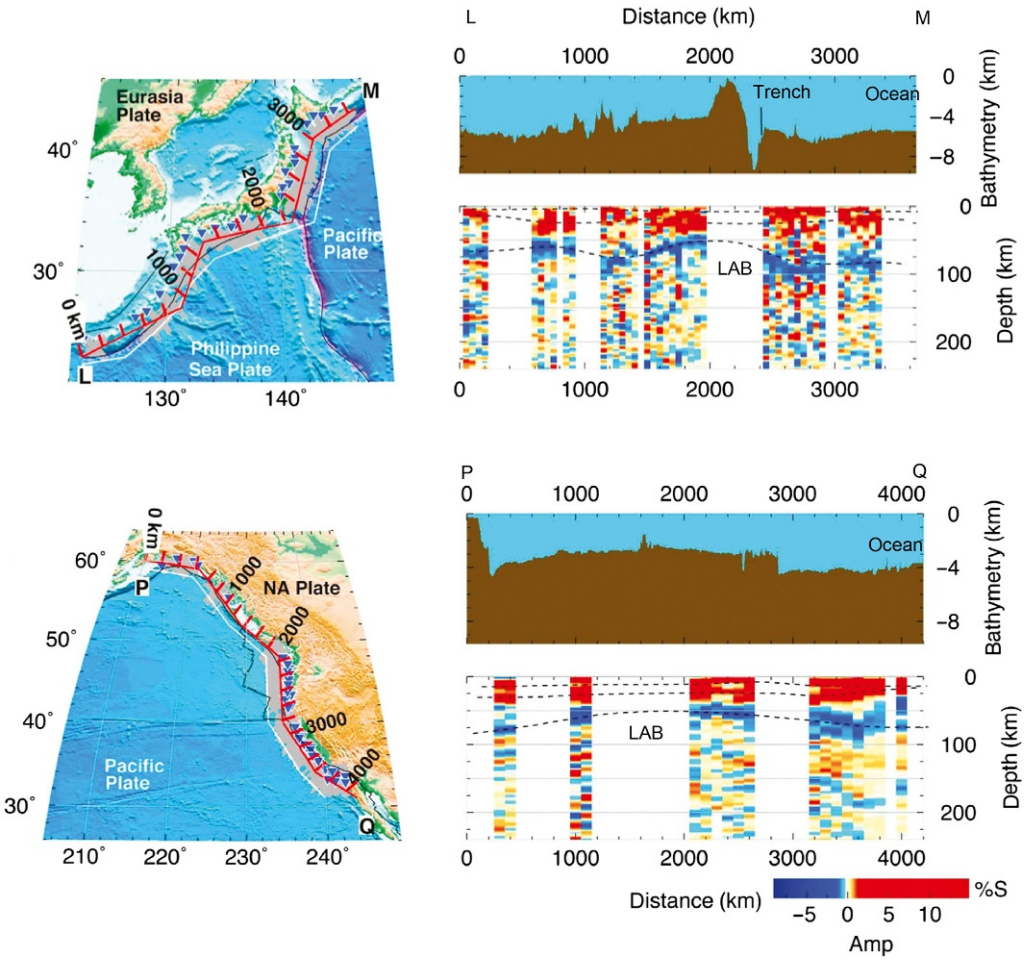

Figure 12 Sp receiver function constraints on the depth of the oceanic LAB near Pacific subduction zones. (left) Map views where red lines show the locations of Sp profiles that make up the images shown on right. Gray-shaded symbols are Sp conversion points at a depth of 100 km. Inverted blue triangles are seismic stations. (right) Sp receiver function images from (a) Japan and (b) western North America. Red corresponds to a positive discontinuity, and blue to a drop in velocity with depth. Negative phases at depths of 40–100 km are interpreted as the LAB. Seafloor bathymetry is shown in the profile above each receiver function image measured at the location of the white lines in the map views. Reproduced from Kumar P and Kawakatsu H (2011) Imaging the seismic lithosphere–asthenosphere boundary of the oceanic plate. *Geochemistry*, *Geophysics*, *Geosystems* 12, Q01006, http://dx.doi.org/10.1029/2010GC003358, Copyright 2011 by the American Geophysical Union, with permission of John Wiley & Sons.

negative discontinuity at depths comparable to the base of the oceanic lithosphere. The depth of this phase varies from 45 to 85 km, and although lithospheric thicknesses in the age range of 40–100 Ma exhibit significant scatter, they also show a broad trend of increasing thickness with age (Kumar and Kawakatsu, 2011) (squares and diamonds in **Figure 11**). This trend, however, shows less variation with age than predicted by a given isotherm, particularly for ages >30 Ma (Kumar and Kawakatsu, 2011). The velocity gradients implied by these data are large and sharp, for example, velocity drops of 7–8% over less than 10–15 km for Ps and Sp phases from the LAB beneath the Philippine and Pacific Plates near Japan (Kawakatsu et al., 2009), leading these authors to propose the presence of horizontal sheet-like partial melts in the asthenosphere.

SS precursors that sample the Pacific add additional layers of complexity to apparent oceanic LAB depths. SS precursors are sensitive to discontinuity structures near the midpoint of the path (**Figure 8**). SS precursors in relatively long-period waveforms (Rychert and Shearer, 2011) indicate a negative discontinuity whose depth, despite some scatter, increases from ~25 km at younger crustal ages (<20 Ma) to ~130 km at ages of >120 Ma (open circles and ×'s in **Figure 11**). These data indicate a negative velocity gradient over less than 20–30 km, except for the deepest discontinuities beneath the oldest crust, which are more consistent with negative velocity gradients over ~60 km (Rychert and Shearer, 2011; Rychert et al., 2012b). SS precursors at shorter periods (Schmerr, 2012) also found a negative mantle discontinuity, but with a less pronounced age dependence (40–100 km, with many observations grouped near 55 and 75 km depth; Rychert et al., 2012b; triangles in **Figure 11**) and only in regions with hotspots or other magmatic activity. Where the discontinuity is imaged, the frequency content of these data implies a velocity gradient over less than 20 km, leading Schmerr (2012) to invoke asthenospheric partial melt; where the discontinuity is not observed, more gradual gradients are implied. Discontinuity depths in Schmerr (2012) are broadly

similar to those from the circum-Pacific Sp and Ps studies (Kawakatsu et al., 2009; Kumar and Kawakatsu, 2011; Kumar et al., 2011).

As discussed by Rychert et al. (2012b), some of the discrepancies between apparent negative discontinuities in the different scattered and reflected phase studies may be explained by the varying resolution afforded by different phase types and frequency content. For example, long-period SS precursors average structure over broader lateral and depth ranges near the discontinuity than either the shorter period SS precursors or the Sp and Ps receiver functions. In addition, whereas SS, Sp, and Ps phases sample discontinuity structure around a given reflection or conversion point, models based on ScS reverberations (Bagley and Revenaugh, 2008; Revenaugh and Jordan, 1991), joint inversions of ScS reverberations and surface and body wave phases (Gaherty et al., 1996, 1999), and multiple-bounce S phases (Tan and Helmberger, 2007) should be viewed as path averages. Rychert et al. (2012b) also point out that varying sensitivities to anisotropic discontinuity structure may produce differences between phase types and as a function of frequency.

1.18.4.3 Synthesis of Seismological Constraints

Despite some unresolved discrepancies between different studies, the general picture that emerges from oceanic imaging is that two types of LAB-related structures exist. One is a significant negative velocity gradient, or perhaps multiple negative gradients, in the 50–80 km depth range that are localized enough in depth (< 15–20 km) to give rise to converted and reflected phases at shorter periods (Kawakatsu et al., 2009; Kumar and Kawakatsu, 2011; Kumar et al., 2011; Schmerr, 2012) (**Figure 11**). The second type of structure corresponds to the age-dependent increases in high-velocity lid thickness, lid shear velocity, and asthenospheric velocity described in the section on tomographic studies (**Figures 9** and **10**). If the lower part of this temporally growing high-velocity layer contains a negative velocity gradient that occurs over ~60 km in depth, it could explain the age-dependent increase in negative discontinuity depth invoked by long-period SS precursors (Rychert and Shearer, 2011). This general picture does pose some challenges. For example, if a vertically localized (< 15–20 km) discontinuity at 50–80 km is present ubiquitously, it should be reflected in long-period SS precursors. However, Rychert et al. (2012b) point out that well-resolved discontinuity depth conflicts in overlapping areas of the Pacific between different studies are actually relatively sparse. In addition, if multiple discontinuities do exist in one region, modeling is required to understand how the phases from each of them would interfere, potentially masking the appearance of one or more of the discontinuities in different types of data.

Until these uncertainties are resolved, the origins of LAB-related velocity structures beneath the oceans cannot be fully understood. However, taking the observations in **Figure 11** at face value, successful models will likely combine processes that explain both a negative discontinuity at a depth of 50–80 km that exists even at very young ages in short-period SS precursors (Schmerr, 2012) (**Figure 11**), such as a dry, depleted compositionally defined lithosphere formed by melt extraction at the ridge, and a thermal boundary layer that grows in depth below the base of the dry, depleted layer at the oldest oceanic crustal ages and that matches tomographic models. Vertical velocity gradients at the base of a compositionally defined layer that is also relatively impermeable could be enhanced by the presence of partial melt. Partial melt confined below solidii could also produce strong vertical velocity gradients within the thermal boundary layer in the more hydrated, less depleted asthenosphere below the compositionally defined layer. Although the deepest negative discontinuity observations from long-period SS phases below old oceanic crust appear to be consistent with a velocity gradient that is relatively gradual in depth (distributed over ~60 km) (Rychert and Shearer, 2011), a more vertically localized velocity gradient (over <30 km) produced by melt concentration in a broader thermal boundary layer could help to explain other observations, such as the 100–110 km deep discontinuities invoked by ScS reverberations (Bagley and Revenaugh, 2008). To conceptualize such a model, consider adding the effects of a dry, depleted layer that is ~50 km thick to the solidus diagram of Hirschmann (2010) in **Figure 9**. Such a model would be broadly consistent with conductivity models derived from inversion of magnetotelluric data. The presence of a dry, depleted layer would explain the constant depth to the top of the high-conductivity layer observed near the East Pacific Rise (Baba et al., 2006; Evans et al., 2005), and melt below an impermeable solidus-defined LAB has been proposed on the basis of a high-conductivity layer below the oceanic lithosphere subducting beneath Central America (Naif et al., 2013).

In this context, discontinuity depths of less than ~40 km from long-period SS precursors at young crustal ages require an additional mechanism. One option has been proposed by Karato (2012) who suggests that within a dry, depleted layer at a young crustal age, a negative velocity gradient associated with the grain boundary sliding relaxation peak will follow the ~1300°K isotherm. If the gradient is distributed over a depth interval just at the outer edge of the range (~10–20 km) quoted by Karato (2012) for young oceanic lithosphere, it could be sharp enough to produce long-period SS precursors (Rychert and Shearer, 2011), but not short-period SS precursors (Schmerr, 2012). In older oceanic mantle, Karato (2012) proposes that the transition from unrelaxed to relaxed velocities will create an even more localized velocity drop at the boundary between the dry lithospheric layer and the hydrated mantle below, enhancing the visibility of this discontinuity even for relatively cool geotherms. However, the relaxation peak model alone is not obviously consistent with the deepest (> 100 km) observations of long-period SS precursors and ScS reverberation discontinuities in old oceanic mantle.

1.18.5 The Seismological LAB Beneath Continents

Compared to the oceanic mantle, the seismic properties of the mantle lithosphere and LAB beneath continents exhibit much greater diversity than is found beneath the oceans. This structural complexity can largely be explained by the longer and more varied tectonic, thermal, and magmatic histories recorded in different continental regions. A first-order feature of continental mantle seismic structure is the profound difference between the thick high-velocity lithosphere of cratonic

regions that have experienced little to no tectonic activity since the end of the Proterozoic (~550 Ma) and the thinner mantle lithosphere observed beneath regions that have experienced tectonic reworking during the Phanerozoic (<~550 Ma). Globally, the thick cratonic mantle lithosphere stands out as a region of unusually high mantle velocity and low attenuation (e.g. Dalton et al., 2009; Dalton and Faul, 2010) (**Figure 4**). A recent adjoint tomography model from Europe (Zhu et al., 2012) offers a particularly striking example of the contrast in SV shear-velocity structure between the stable Eastern European Platform to the northeast of the Tornquist–Teisseyre Zone, where high velocities exist to depths of 175 km and more, and the more recently tectonized regions of Europe (**Figure 13**). The next section explores the character and possible origins of the LAB beneath cratons and the following section focuses on the LAB beneath Phanerozoic continents.

1.18.5.1 Cratons

A key question to address regarding the cratonic LAB is whether a low-velocity asthenospheric layer even exists beneath cratons. In tomographic models, lateral variations in velocity between cratonic and non-cratonic regions often extend to depths of 300–400 km, as shown beneath the Eastern European craton (**Figure 13**; Zhu et al., 2012). However, these deep lateral variations need to be considered in the context of absolute

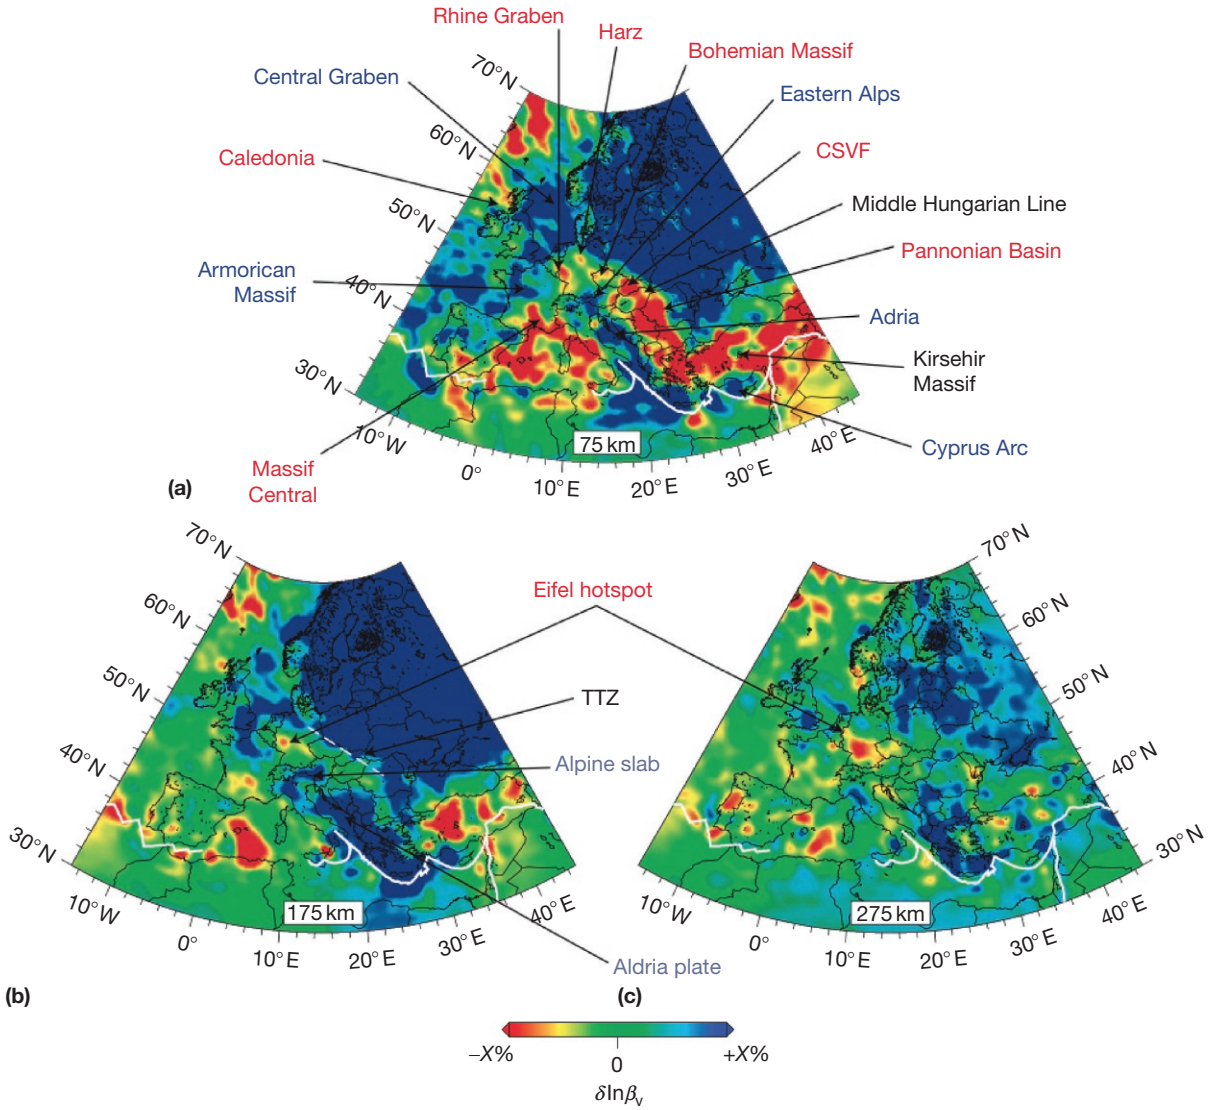

Figure 13 A model of shear-wave velocity beneath Europe that highlights anomalously high velocities in the mantle lithosphere beneath the Eastern European craton. Map views at depths of (a) 75 km, (b) 175 km, and (c) 275 km. The model includes radial anisotropy, and SV velocities are shown as perturbations to a one-dimensional background model and range from −4% to +4% in (a) and −3% to +3% in (b) and (c). The Tornquist–Teisseyre Zone (dashed line labeled TTZ in (b)) separates the Eastern European craton (to the northeast) from more recently tectonized regions of Europe. Reprinted from Zhu H, Bozdag E, Peter D, and Tromp J (2012) Structure of the European upper mantle revealed by adjoint tomography. *Nature Geoscience* 5: 493–498, by permission from Macmillan Publishers, Copyright 2012.

velocity. For example, beneath the Eastern European craton, absolute isotropic shear velocity decreases from a maximum at a depth of ~150 km to a deeper lower-velocity layer (Zhu and Tromp, 2013). More broadly, in many global and regional models that employ surface waves or long-period waveforms, absolute isotropic shear velocity reaches a minimum in the 200–300 km depth range, which is consistent with the existence of a low-velocity asthenosphere below a high-velocity cratonic lithosphere. Some studies have found that a minimum is not required in both SV and SH absolute velocity beneath cratons (Gaherty and Jordan, 1995; Gaherty et al., 1999), and others have shown that at depths greater than 200 km, fundamental mode surface waves may not have the sensitivity to resolve the presence of a low-velocity layer (Pedersen et al., 2009). Nonetheless, in recent tomographic models that include longer period fundamental mode surface waves (Nettles and Dziewoński, 2008) and overtones (Lekic and Romanowicz, 2011a,b), the average isotropic velocity does decrease below a high-velocity lithospheric layer, before increasing again into the deeper upper mantle. In the Lekic and Romanowicz (2011a,b) model, the velocity profile cluster that corresponds to cratons contains a negative velocity gradient at depths of 190–250 km that would correspond to a seismological LAB (**Figure 5(b)**). A low-velocity layer beneath the cratonic lithosphere has also been resolved in compressional wave velocities beneath North America (Chu et al., 2012a, in press).

Minimum velocities in the sub-cratonic low-velocity 'asthenospheric' layer are not as low as those observed in the asthenosphere beneath oceans or younger continental regions (e.g., the shear-velocity profiles in **Figure 5(b)**). Part of this difference is explained by the greater pressures in the sub-cratonic asthenosphere, but a cooler mantle potential temperature could also exist beneath some cratons (Ford, 2013). Alternatively, the sub-cratonic asthenosphere may have a lower volatile and/or melt content relative to the asthenosphere beneath younger continental regions and the oceans, or the expression of volatiles and melt in absolute velocity may be relatively muted at the temperatures and pressures of the sub-cratonic asthenosphere.

While the cooling associated with the cratonic lithosphere may extend below the seismological LAB (as defined by a drop in absolute velocity), perhaps in the form of small-scale convection (e.g., King and Ritsema, 2000), anomalously cold temperatures do not appear to reach the transition zone beneath cratons on a widespread basis, although conflicting results exist for some regions. If temperatures at transition zone depths were, in general, systematically lower beneath cratons than elsewhere, the depth of the '410 km' velocity discontinuity would be shallow relative to other regions. If the thermal perturbation reached still deeper, the '660 km' discontinuity would be offset to greater depths. Beneath the North American craton, several studies of transition zone discontinuities have concluded that anomalously cold temperatures do not reach the '410' discontinuity (Bostock, 1996; Li et al., 1998; Thompson et al., 2011). A number of studies reached a similar conclusion for cratons globally (Chevrot et al., 1999; Flanagan and Shearer, 1998; Lawrence and Shearer, 2006) but others did not (Gossler and Kind, 1996; Gu and Dziewonski, 2002). Thermal perturbations at transition zone depths beneath other individual cratons, for example, Southern Africa (e.g., Blum and Shen, 2004; Gao et al., 2002), are debated. See **Chapter 1.21** for more on this topic.

Anisotropy in seismic velocities provides another piece of evidence for the existence of an asthenosphere beneath cratons. Radial anisotropy with a slow vertical symmetry axis is common beneath the cratonic lithosphere, and is consistent with horizontal shearing, as is the case beneath the oceanic asthenosphere (e.g., Gung et al., 2003). Resolution of azimuthal anisotropy in the sub-cratonic asthenosphere is more challenging. Based on a global surface wave inversion, Debayle et al. (2005) argued that a layer of significant anisotropy created by shearing due to plate motion was resolved only beneath Australia (**Figure 5** in **Chapter 1.19**); their conclusions for Australia are consistent with azimuthal anisotropy in regional models (Debayle and Kennett, 2000; Simons and van der Hilst, 2003; Simons et al., 2002). More recently, however, combined long-period waveforms and SKS splitting inversions across North America (Marone and Romanowicz, 2007; Yuan and Romanowicz, 2010a,b) and regional inversions from Canada and the United States (Chen et al., 2007; Darbyshire and Lebedev, 2009; Darbyshire et al., 2013; Deschamps et al., 2008; Snyder and Bruneton, 2007) have indicated the presence of azimuthal anisotropy beneath the mantle lithosphere of the North American craton whose fast direction is consistent with shear in the direction of absolute plate motion. Yuan and Romanowicz (2010a,b) proposed that a rotation in the direction of azimuthal anisotropy from the deep mantle lithosphere to the asthenosphere provides an alternative means of mapping the position of the seismological LAB, at least under North America (**Figure 14**).

How gradual is the negative velocity gradient beneath the cratonic lithosphere? Compared to the oceanic LAB, or the LAB in Phanerozoic continental regions, the LAB velocity gradient beneath most cratons appears to be weaker and more gradual. The clearest evidence comes from converted wave studies, which provide tighter constraints on the depth extent of the cratonic LAB velocity gradient than the surface wave tomography and P waveform modeling described earlier.

A global analysis of Ps receiver functions did not resolve a clear negative polarity conversion from the LAB of any cratonic region (Rychert and Shearer, 2009), suggesting that a significant velocity drop in absolute shear velocity at the cratonic LAB, such as the gradients observed in tomographic models (e.g., **Figure 5(b)**), would need to be distributed over depth ranges of 15–20 km or more. Ps phases consistent with anisotropic discontinuities have been observed in the LAB depth range (170–230 km) near the base of the thick lithosphere of the Slave craton (Bostock, 1998; Snyder, 2008). However, these phases indicate layered structures that are more complex than a simple, single gradient from a high-velocity mantle lithosphere to a low-velocity asthenosphere.

Because of the longer periods at which they are typically analyzed, Sp conversions are sensitive to more gradual velocity gradients. For example, at a dominant period of 10 s and for velocity drops of 5–8%, the absence of significant 'negative' Sp phases would indicate negative velocity gradients distributed over ~50 km or more, and the presence of a clear Sp phase would indicate a velocity gradient over ~30 km or less (Ford et al., 2010); see Rychert et al. (2007, 2010) for additional

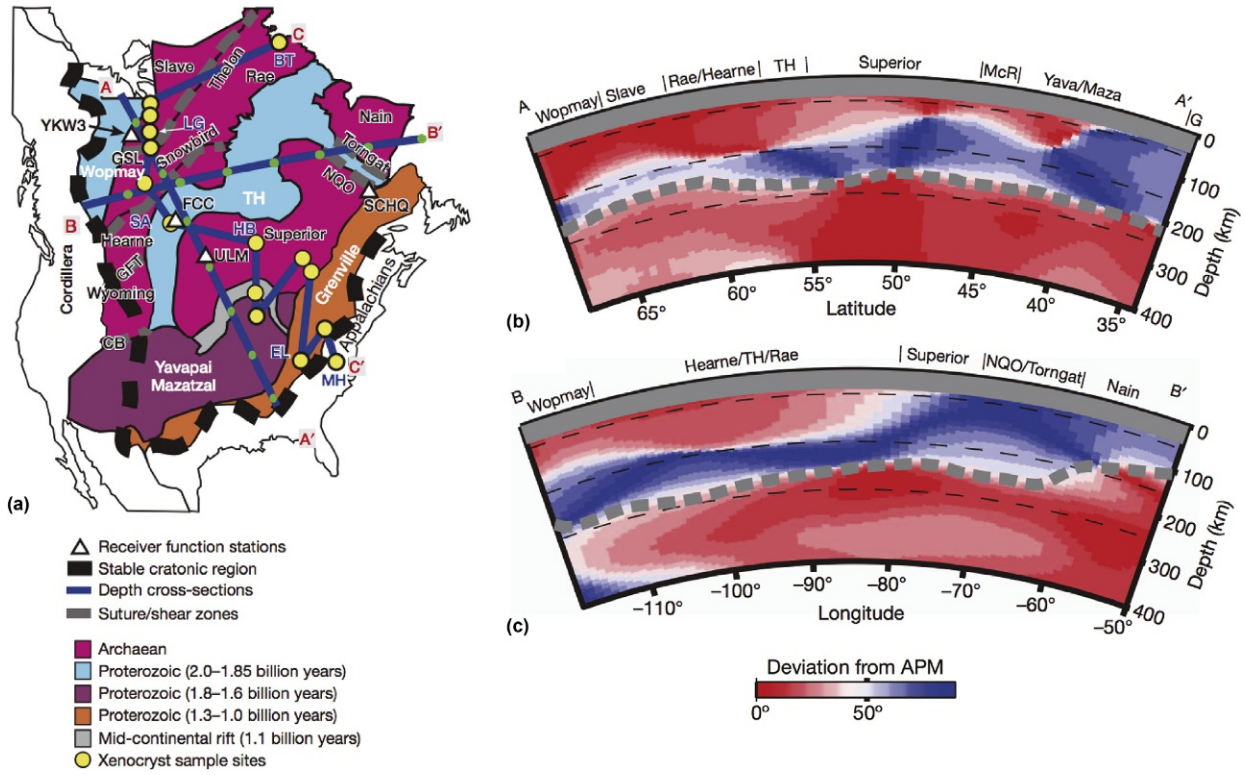

Figure 14 A shear-velocity model for North America that includes radial and azimuthal anisotropy. (a) Precambrian basement age. Blue lines marked A–A′ and B–B′ show the locations of profiles in (b) and (c). (b, c) Vertical profiles showing the fast axis of azimuthal anisotropy. Colors show the fast axis orientation relative to North American absolute plate motion in the Pacific hotspot reference frame. Two layers with distinct fast axis orientations exist within the cratonic mantle lithosphere, and a rotation of the fast axis toward absolute plate motion occurs at greater depths, consistent with shear in the asthenosphere produced by plate motion. The gray dashed line shows the LAB as defined by this latter fast axis rotation. Reprinted from Yuan H and Romanowicz B (2010) Lithospheric layering in the North American craton. *Nature* 466: 1063–1068, http://dx.doi.org/10.1038/nature09332, by permission from Macmillan Publishers: Nature, Copyright 2013.

examples of Ps and Sp velocity gradient sensitivity. Sp conversion studies have the advantage that they are free of potential contamination from crustal multiples that may overprint Ps phases at mantle depths. However, Sp imaging becomes progressively more challenging with depth, a point of particular relevance to imaging the cratonic LAB. The ray parameter range for which Sp conversions have incidence angles less than the critical incidence angle decreases as conversion depth increases, thus reducing the low end of the range of epicentral distances from which Sp phases from direct S waves can be observed. Nonetheless, in regions where data from larger direct S epicentral distances are abundant, high-quality Sp imaging at depths of ~200 km is possible. Some studies add SKS waveforms (i.e., SKSp phases) to augment data in the low ray parameter range, but SKS phases can also be problematic because of lower signal-to-noise ratios or contamination from other teleseismic phases (Wilson et al., 2006).

Reports of Sp conversions from the base of different cratonic lithosphere are variable, and, when sighted, these phases are, in general, of lower amplitude and less clear than Sp conversions from the shallower LAB depth ranges typical of younger continental regions. Beneath central United States and Canadian cratonic regions of North America, the Sp analyses of Abt et al. (2010), Kumar et al. (2012), and Kind et al. (2012) found no evidence for Sp energy that was coherent over large areas from the LAB depth range (150–250 km as defined by the negative velocity gradients in surface wave tomography). LAB Sp phases have been identified beneath Canada (Miller and Eaton, 2010), on an intermittent basis beneath the Wyoming craton (Hopper et al., in press; Lekic and Fischer, in press), and beneath portions of the cratonic central United States (Foster et al., in press; Hansen et al., 2013), but these phases are of relatively low amplitude, and beneath other regions of the central United States craton, no LAB Sp phase is observed (Foster et al., in press). Beneath cratonic regions of central and western Australia, Ford et al. (2010) found no clear Sp phases from the tomographically defined LAB depth range, although LAB phases at depths of ~130 km were seen at the eastern edge of the craton. These results differ from those of Kumar et al. (2007) who did observe deep potential LAB Sp phases beneath cratonic Australia. At the base of the Indian cratonic lithosphere, no evidence for a strong, localized velocity gradient was found from Sp converted phases (Bodin et al., 2014). Sp arrivals have been associated with the LAB beneath the eastern European craton/Baltic shield at depths of 200 km and more (Geissler et al., 2010; Sacks et al., 1979), although Geissler et al. (2010) point out that these phases are relatively weak and complex, and are missing at some stations.

In some cases, LAB velocity gradients at the base of thick cratonic lithosphere may be enhanced by asthenosphere with

lower velocities than typical of sub-cratonic regions. Deep Sp phases from the LAB depth range defined by surface wave tomography have been observed beneath the Arabian platform (Hansen et al., 2007; Mohsen et al., 2006) and Tanzania (Wölbern et al., 2012). The proximity to rifting in these cases raises the possibility of unusually low velocity asthenosphere (Fishwick, 2010; Weeraratne et al., 2003), which would contribute to the observability of LAB Sp phases. The situation beneath the Kalahari craton is more complex. Several surface wave tomography studies have found a high-velocity lithospheric layer bounded from below by a negative shear-velocity gradient starting at a depth of 160–175 km (Li and Burke, 2006; Priestley and Tilmann, 2009; Priestley et al., 2006). Sp conversion studies suggest negative Sp phases in two different depth ranges, 150–160 km (Hansen et al., 2009; Savage and Silver, 2008) and 200–300 km (Kumar et al., 2007; Wittlinger and Farra, 2007), and Ps and SKS phases have been modeled in terms of a rapid transition in azimuthal anisotropy at ~160 km (Vinnik et al., 2012). These phases could represent locally steep negative velocity gradients within a broader LAB region, but the dominant periods in these studies differ, and care must be taken to account for this frequency dependence in their interpretation. Whole mantle tomographic models suggest that warm upwelling mantle impinges on the base of the cratonic lithosphere in southern Africa (e.g., Ritsema et al., 2011), and if the upwelling produces a larger and/or more localized LAB velocity gradient relative to other cratons, higher amplitude Sp phases will be generated. Depending on how far north the influence of this upwelling extends, it could also contribute to the LAB phases apparent beneath the Tanzanian craton and Arabian platform.

Where no Sp or Ps phase is observed from the cratonic LAB, the drop in velocity from lithosphere to asthenosphere indicated by surface wave or long-period waveform tomography must be gradual in depth, that is, distributed over ~50 km or more. In these cases, the negative shear-velocity gradient is consistent with models where velocity depends only on temperature, although gradual gradients in composition or melt cannot be ruled out. For example, although rates of water diffusion are modest (Hirth and Kohlstedt, 1996), initially localized gradients in water content could broaden over time, with maximum length scales of ~50 km over ~2 billion years. Where Sp phases are present, but are relatively weak and intermittent, they indicate some localized sharpening of negative shear-velocity gradients over vertical length scales of ~30 km or less, perhaps because of variations in bulk composition, volatile content, or melt. When interpreting differences in Sp phase amplitude or spatial continuity between cratons, the possibility that deeper mantle upwelling may have produced unusually low asthenospheric velocities should be considered.

While the evidence for gradual versus localized LAB velocity gradients varies from craton to craton, numerous types of seismological observations point to discontinuities and layering internal to the cratonic mantle lithosphere. Sp and Ps phases consistent with negative velocity gradients have been observed on a widespread basis within the cratonic mantle lithosphere, often at depths of 60–120 km (Abt et al., 2010; Bodin et al., 2014; Chen et al., 2009; Ford et al., 2010; Foster et al., in press; Geissler et al., 2010; Hansen et al., 2013; Hopper et al., in press; Kind et al., 2012; Kumar et al., 2012; Lekic and Fischer, in press; Miller and Eaton, 2010; Rychert and Shearer, 2009; Wölbern et al., 2012; Zurek and Dueker, 2005), and discontinuities at comparable depths have also been characterized as anisotropic boundaries using both Ps (Bostock, 1998; Levin and Park, 2000; Mercier et al., 2008; Saul et al., 2000) and Sp (Ford, 2013) data. A low-velocity layer with its top at ~100 km is also a consistent feature of cratonic models based on the '8° discontinuity in long-range seismic profiles' (Nielsen et al., 2002; Thybo, 2006; Thybo and Perchuc, 1997) and in regional P waveforms (Chu et al., 2012a). Finally, surface wave studies have resolved vertical variations in azimuthal anisotropy within the cratonic mantle lithosphere, including cases from North America (Darbyshire et al., 2013; Yuan and Romanowicz, 2010a) and Europe (Zhu and Tromp, 2013). For example, Yuan and Romanowicz (2010a) found that a pronounced rotation of fast azimuth orientation defines two distinct layers of azimuthal anisotropy within the North American cratonic mantle (**Figure 14**). The depth range of this vertical rotation in fast azimuth coincides with the depth extent of the negative Sp energy observed at many cratonic stations (Yuan and Romanowicz, 2010a; Yuan et al., 2011). Overall, further work is required to explore the resolution and consistency of all the data types that point to vertical layering within the cratonic mantle lithosphere, and to determine whether the various observations from a given region can be explained by the same structural model. Progress in this area will provide constraints on the processes that formed the cratonic mantle lithosphere (e.g., Bostock, 1998; Chen et al., 2009; Darbyshire et al., 2013; Snyder, 2008; Yuan and Romanowicz, 2010a; Zhu and Tromp, 2013), and on the possibility of its later deformation (e.g., Eaton and Frederiksen, 2007).

1.18.5.2 Phanerozoic Continental Regions

In contrast to cratons, much of the lithosphere in Phanerozoic continental regions appears to have a LAB velocity gradient that is well localized in depth. Numerous studies have found clear Sp and Ps phases that emanate from the depth range of the transition from high-velocity lithosphere to low-velocity asthenosphere defined by surface wave tomography and regional waveform modeling. Examples include global studies (Rychert and Shearer, 2009) and regional analyses spanning the western United States (Abt et al., 2010; Bailey et al., 2012; Hansen et al., 2013; Hopper et al., in press; Kind et al., 2012; Kumar et al., 2012; Lekic and Fischer, in press; Lekic et al., 2011; Levander and Miller, 2012; Levander et al., 2011; Li et al., 2007); the Phanerozoic eastern United States (Abt et al., 2010; Rychert et al., 2005, 2007); South America (Heit et al., 2007); Greenland (Kumar et al., 2005a); Europe (Geissler et al., 2010; Miller and Agostinetti, 2011, 2012; Sodoudi et al., 2006a); the Middle East (Angus et al., 2006; Hansen et al., 2007; Mohsen et al., 2006; Ozacar et al., 2008), the Himalayas, Tibet, and the Tien Shan (Devi et al., 2011; Kumar et al., 2005b; Oreshin et al., 2002; Xu et al., 2011; Zhao et al., 2011); China (Chen, 2009; Chen et al., 2006; Sodoudi et al., 2006b); and Australia (Ford et al., 2010; Kumar et al., 2007). See Rychert et al. (2010) and Fischer et al. (2010) for reviews. As previously mentioned, the presence of significant LAB phases in Sp receiver functions typically implies an LAB velocity gradient that is localized over 30 km in depth or less, although waveform modeling that accounts for the actual frequency content of the data is required for accurate

velocity gradient estimates (e.g., Ford et al., 2010). Large LAB phases in Ps receiver functions indicate even sharper gradients, for example, velocity drops of 5–8% over less than 11 km in the northeastern United States (Rychert et al., 2005, 2007). LAB velocity gradients with this degree of depth localization are difficult to reconcile with creation of the LAB by temperature gradients alone, except in regions with focused upwelling. Rather, they point to enhanced volatile content and less depletion in the asthenosphere relative to the lithosphere, and/or to partial melt in the asthenosphere just below the LAB.

Variations in the apparent depth and character of the seismological LAB across tectonically distinct regions shed additional light on the origin and rheological significance of the LAB velocity gradient. For example, beneath Phanerozoic continental regions that have undergone significant extension, the LAB is typically shallower than beneath surrounding unextended lithosphere (Chen et al., 2006; Geissler et al., 2010; Lekic et al., 2011). However, the character of the LAB can differ significantly between rifted regions.

Beneath southern California, a distinct negative phase is observed in Sp receiver functions (Lekic et al., 2011) (**Figure 15(a)**); its depth varies from 40 km to 95 km and correlates well with the depth range of the LAB velocity gradient from surface wave tomography (Rau and Forsyth, 2011) (**Figure 15(b)**). In addition, the shear-velocity drop implied by the negative Sp phase ($8 \pm 3\%$ if it occurs instantaneously in depth) accounts for the amplitude of the LAB velocity gradient in the tomography, indicating that both types of observations reflect the same LAB velocity structure. However, the Sp phases require that the LAB velocity gradient is sufficiently localized in depth (<20–30 km) that asthenospheric velocities need to be reduced relative to the lithosphere by a mechanism such as enhanced volatile or partial melt content, in addition to the effects of temperature. Lateral variations in the depth of the LAB velocity gradient provide additional constraints on LAB properties. The depth of the LAB Sp phase is 20–30 km shallower beneath the Salton Trough and Inner Borderland, regions that have experienced significant extension, relative to

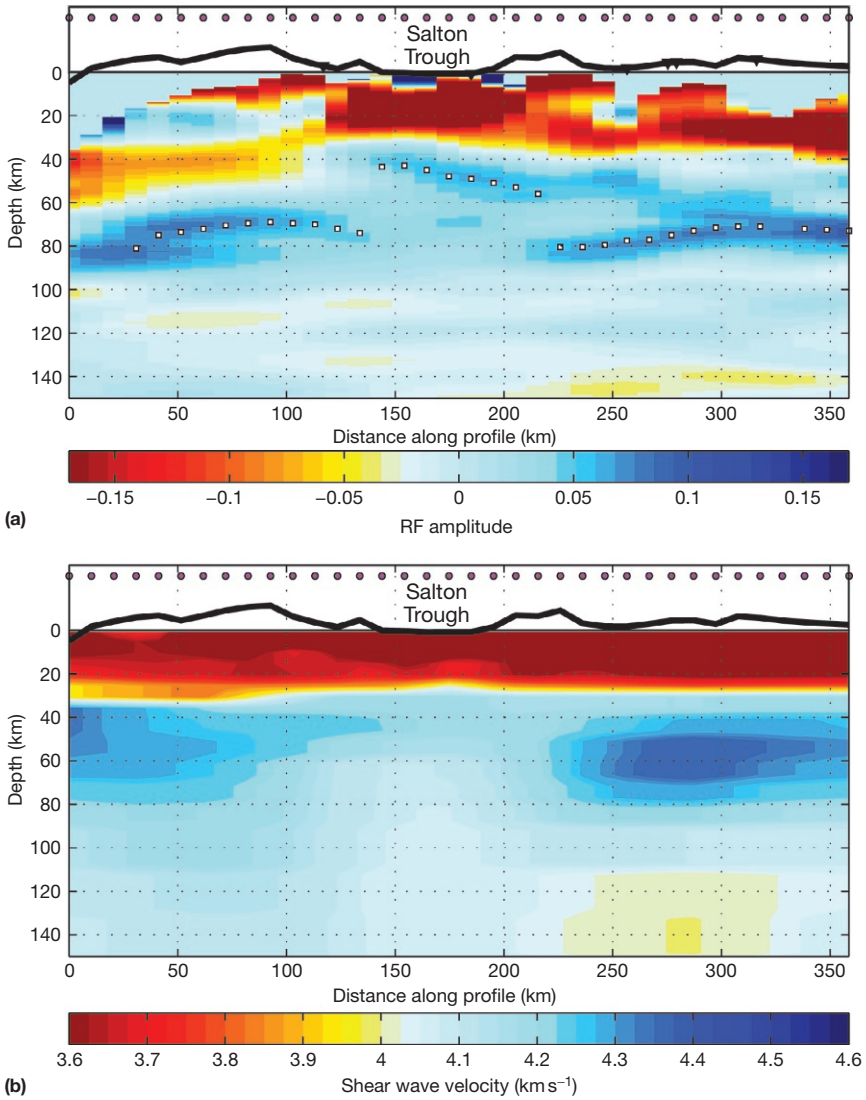

Figure 15 (Continued)

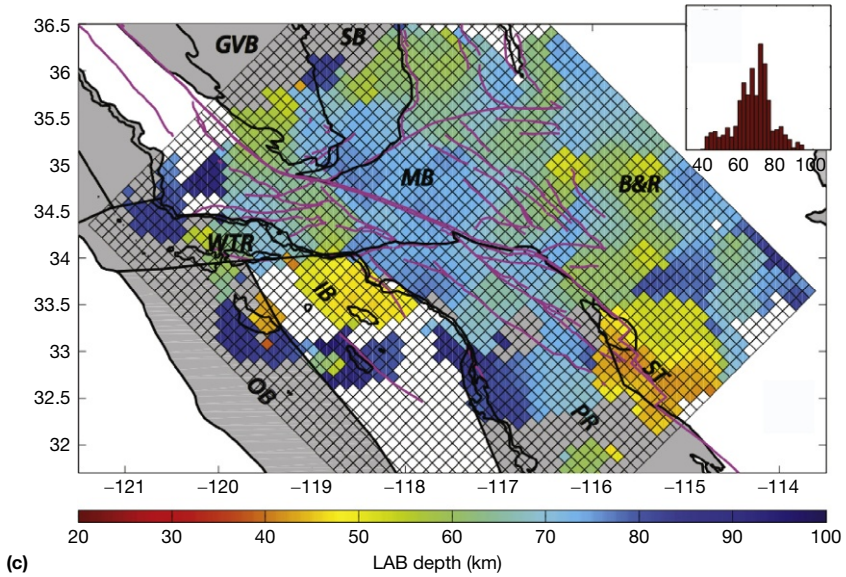

Figure 15 Models of lithospheric structure in southern California that illustrate the good correlation between LAB depth estimates from Sp phases (a, c) and Rayleigh waves (b). (a) Vertical profile through the Sp receiver function common conversion point stack of Lekic et al. (2011); profile passes through the southern Salton Sea and is oriented parallel to the axis of the model grid in (c) that is roughly normal to the coast. Warm colors indicate a velocity increase with depth; at depths of <40 km, these interfaces correspond to the base of sediment or crust. Cool colors indicate a velocity decrease with depth. The largest amplitude velocity decrease falls in the depth range of the transition from high lithospheric shear velocities to lower asthenospheric velocities in (b) and is interpreted as the LAB (white squares). Surface topography (black line) is exaggerated tenfold. (b) Vertical profile in the same location as (a) from the SV shear-velocity model of Rau and Forsyth (2011). (c) Map of depth to the LAB from Lekic and Fischer (2011). Outer Continental Borderland (OB); Inner Continental Borderland (IB); Peninsular Ranges (PR); Western Transverse Range block (WTR); Mojave block (MB); Basin and Range (B&R); Sierra Block (SB); Great Valley block (GVB), and the Salton Trough (ST). Pink lines delineate surface traces of major faults. Inset shows histogram of LAB depths. Parts (a) and (c) reprinted from Lekic V, French SW, and Fischer KM (2011) Lithospheric thinning beneath rifted regions of Southern California. *Science* 334: 783–787, doi: 10.1126/science.1208898, with permission from AAAS.

the LAB of adjacent lithosphere, and some of the transitions from thick to thin lithosphere occur over horizontal length scales of 50 km or less (Lekic et al., 2011) (**Figure 15(a)** and **15(c)**). The contrast in viscosity between lithosphere and asthenosphere must, therefore, be great enough to create topography on the LAB with dips of 20–30°. Numerical modeling of lithospheric deformation in response to extension (albeit with simpler extensional geometries than found in the Salton Trough and Inner Borderland) indicates that LAB topography with dips of 30° can be created if the mantle lithosphere, or at least a portion of the mantle lithosphere, resists deformation to a significantly greater degree than the asthenosphere (Gueydan et al., 2008; Huismans and Beaumont, 2003, 2011). In addition, because the lateral extent of the thinned lithosphere beneath the Salton Trough and Inner Borderland is not much broader than the area of crustal thinning and the surface expression of extension, strain in the mantle lithosphere appears to be relatively localized. This style of deformation is observed in numerical models with strain-dependent rheologies (e.g., Gueydan et al., 2008; Huismans and Beaumont, 2003, 2011), and would be consistent with the degree of strain localization predicted by rheologies dominated by damage and pinning of grain growth (Bercovici and Ricard, 2012).

However, LAB structure between rifted continental lithosphere can vary greatly. In contrast to the Salton Trough, where lithosphere with a well-defined negative LAB velocity gradient is ubiquitous, Rychert et al. (2012a) observed a clear negative Sp phase beneath the lithosphere flanking the Ethiopian Rift, but beneath the rift itself they found a positive phase at comparable depths (75 km) (**Figure 16**). They interpreted the positive phase, which corresponds to a velocity increase with depth, as the base of the partial melt zone beneath the rift, whereas the negative phase beneath the flanking lithosphere is consistent with partial melt ponded below an impermeable LAB. These results suggest that the distribution of partial melt, as regulated by solidii and mantle permeability, can dominate the seismic properties of the LAB.

Seismological constraints on the LAB are also adding to our understanding of the growth of the continental lithosphere through collisional processes. For example, several studies have used Sp phases to trace the LAB of the Indian plate as it dips to the north beneath the Himalayas and Tibetan plateau, and to assess its tectonic geometry relative to the Tibetan and Asian lithospheres (Devi et al., 2011; Kumar et al., 2005b; Oreshin et al., 2002; Xu et al., 2011; Zhao et al., 2011). These results suggest that discrete layers of lithosphere can remain relatively intact and coherent even after one underthrusts another over length scales of many hundreds of kilometers. Dipping mantle discontinuities interpreted as the remnants of Proterozoic and Archean lithospheric slabs now embedded in the mantle beneath the Slave craton (Bostock, 1998; Chen

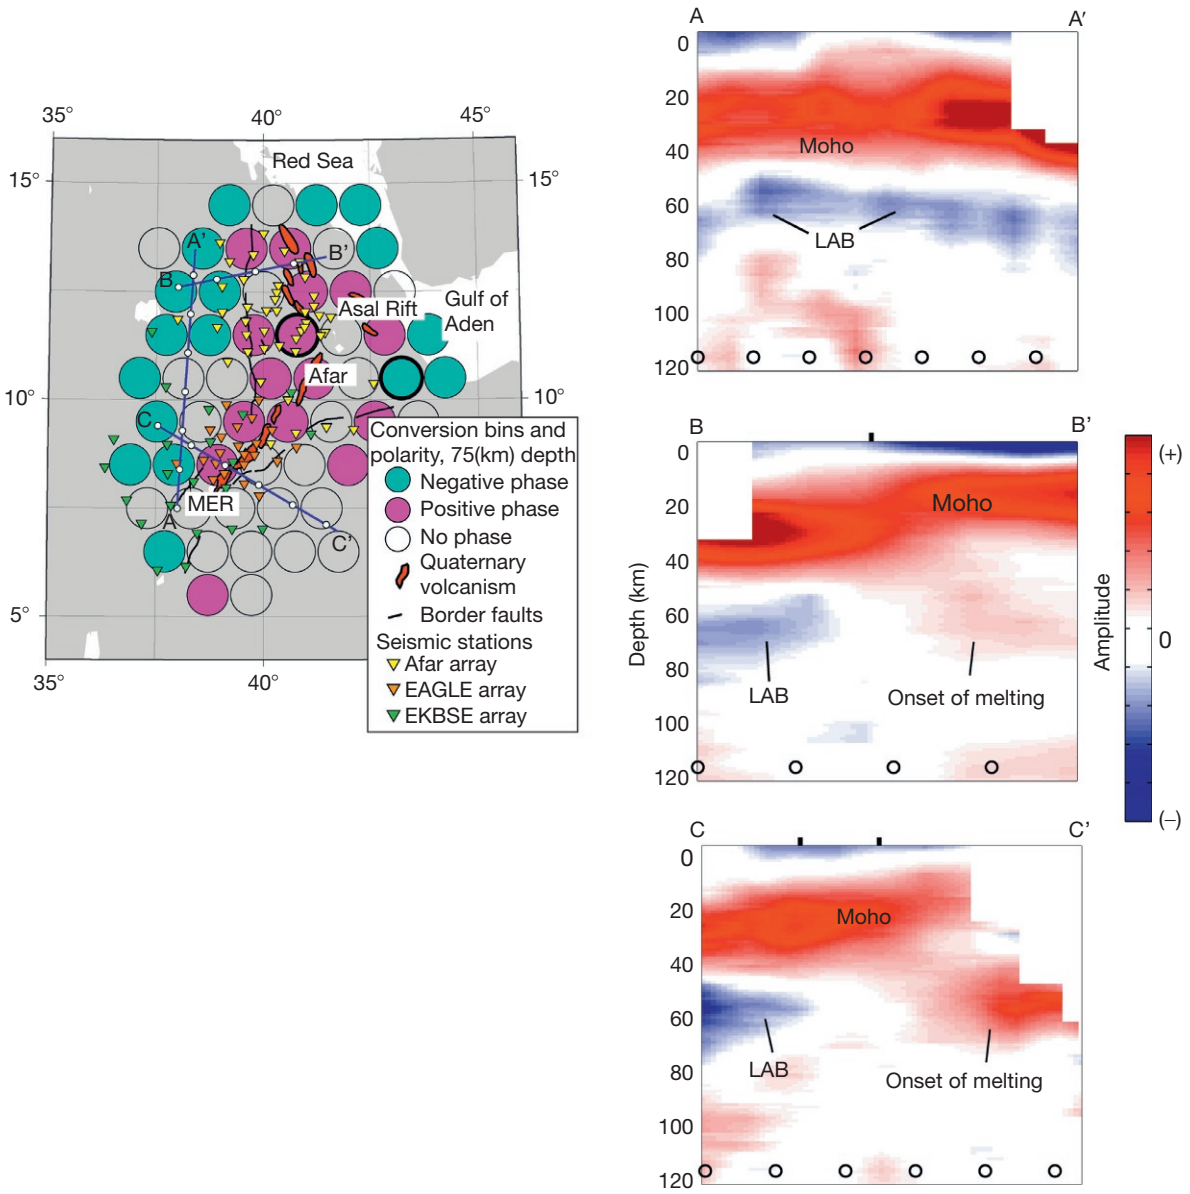

Figure 16 LAB structure across the Ethiopian Rift. (a) Map of Sp phase polarity at 75 km depth with stations shown as inverted triangles. Circles show geographic bins with more than ten waveforms. Blue lines are the locations of profiles in (b). Red areas are Quaternary–Recent volcanic segments. Black lines show border faults. (b) Vertical profile through the Sp receiver function common conversion point stacks. Positive polarity amplitudes are in red (velocity increase with depth) and negative polarity amplitudes are in blue (velocity decrease with depth). et al., 2009; Snyder, 2008) provide evidence that lithospheric imbrication also contributed to the formation of portions of the cratonic mantle lithosphere.

As the density of broadband seismic stations increases, sharper resolution of LAB seismic structure and enhanced understanding of its meaning are sure to follow. For example, the passage of the EarthScope Transportable Array through the western United States has enabled a new generation of tomographic, and scattered and reflected wave imaging of the lithosphere and asthenosphere beneath this tectonically complex region. Nonetheless, much remains to be learned about how regional and teleseismic phases interact with complex, three-dimensional structures, in particular when their finite frequency sensitivity kernels and the effects of anisotropy are considered. Sp and Ps studies of the LAB beneath the western United States that employ Transportable Array data broadly agree on certain features of the seismological LAB, for example, relatively thin lithosphere beneath the Basin and Range (60–80 km) and anomalously thick (120–130 km) lithosphere beneath the central and northern Colorado Plateau (Bailey et al., 2012; Hansen et al., 2013; Hopper et al., in press; Kind et al., 2012; Kumar et al., 2012; Lekic and Fischer, in press;

Lekic et al., 2011; Levander et al., 2011) (**Figure 17**). However, the LAB models provided by these studies often differ significantly at shorter spatial scales. Some of these inter-model variations likely relate to differences in the frequency content retained in the waveforms. Differences in filtering (e.g., applying a low-pass filter with a corner at 6 s versus a corner at 2–4 s to Sp phases) can significantly increase interference with shallower arrivals and bias the apparent depth of shallow mantle discontinuities (Hopper et al., in press). Resolution of lateral changes in LAB structure will also decrease as waveforms become progressively longer period and/or discontinuities become deeper (Lekic et al., 2011). On the positive side, the rich frequency dependence of scattered and reflected wave interactions with three-dimensional velocity gradients holds promise for future improvements to methods for imaging LAB structure.

1.18.6 Conclusions

Beneath oceans and continental regions that experienced significant tectonic activity in the Phanerozoic, the high absolute-velocity lithosphere is underlain by a low absolute-velocity asthenosphere. The weight of recent studies favors the presence of a low-velocity asthenosphere beneath cratonic continental regions as well, even when the effects of anisotropy are accounted for. Hence, a seismological LAB that corresponds to a negative gradient in absolute velocity can be considered a global feature. Its depth varies significantly, ranging from less than 100 km beneath young oceans and tectonically active continental regions to 200–300 km beneath cratons.

The asthenosphere, as defined by low absolute velocities, typically contains significant velocity anisotropy that is consistent with shear because of differential motion relative to the lithosphere. Within the asthenosphere, the minimum shear velocity on average increases with crustal age in the oceans, and from Phanerozoic to cratonic continental regions. These trends are consistent with a cooling of asthenospheric temperatures with increasing crustal age in the oceans and with lower mantle potential temperatures in the asthenosphere beneath cratons than beneath younger continental regions. In this interpretation, tectonically correlated thermal variations would extend below the seismologically defined LAB, perhaps as a result of small-scale convection. However, lateral variations in asthenospheric melt and volatile content and the manner in which they are expressed in seismic velocities should also be considered.

Beneath oceans, two types of LAB-related structures appear to exist: one or more negative velocity gradients in the 50–80 km depth range that are localized in depth (<15–20 km) and age-dependent increases in high-velocity lid thickness, lid shear velocity, and minimum asthenospheric velocity. Oceanic LAB structures point to processes that combine deepening isotherms caused by cooling with those that can produce vertically localized shear-velocity gradients, such as partial melt that

collects beneath an impermeable boundary, or the contrast between a dry, depleted lithosphere and a more volatile-rich and fertile asthenosphere.

LAB velocity gradients beneath most cratons are, in general, weaker and/or more intermittent than those found beneath oceans and Phanerozoic continents. In some studies in cratons, the absence of significant scattered wave phases from LAB depths points to LAB velocity gradients that occur over ~50 km or more, and these gradients would be consistent with thermal gradients alone. In other cases, weak scattered wave phases point to LAB velocity gradients over 30 km or less, indicating vertical variations in bulk composition and/or volatile content, or perhaps partial melt.

Beneath Phanerozoic continental regions, large LAB velocity gradients localized over depth ranges of ~30 km or less are typically observed, indicating the presence of higher volatile or melt content in the asthenosphere relative to the lithosphere, in addition to higher temperatures. In some regions, abrupt horizontal changes in LAB depth bound the strength contrast between lithosphere and asthenosphere in the sense that the lithosphere must be stiff enough to create LAB topography with dips of 20–30° or more.

1.19.1 Introduction

Thirty years ago, the first global isotropic tomographic models of the mantle were published (Dziewonski, 1984; Woodhouse and Dziewonski, 1984). Since that time, many new tomographic models were published, and a large family of techniques was made available. This important progress was made possible by the extensive use of computers that can handle very large datasets and by the availability of high-quality digital seismograms recorded by broadband seismic networks such as GEOSCOPE (Romanowicz et al., 1984), IRIS (Smith, 1986), and all networks coordinated by the FDSN (Federation of Digital Seismograph Networks; Romanowicz and Dziewonski, 1986). The recent years have seen the rapid development of very dense regional broadband seismic networks such as USArray in the United States, VEBSN (Virtual European Broadband Seismograph Network) in Europe, or F-net in Japan. Thanks to the installation of modern digital networks, it is now possible to map the whole earth from the surface down to the center of the Earth by seismic tomography. However, until recently, most tomographic techniques only make use of travel times or phase information in seismograms and very few use the amplitude, even when seismic waveforms are used (Li and Romanowicz, 1996; Woodhouse and Dziewonski, 1984). Global tomographic models have been improved over the years by an increase in the number of data and more importantly by using more general parameterizations, now including anisotropy (radial anisotropy in Nataf et al. (1986) and general slight anisotropy in Montagner and Tanimoto (1990, 1991)) and to a lesser extent anelasticity (Dalton and Ekström, 2006; Romanowicz, 1990; Tanimoto, 1990). Now, with the expansion of fast parallel computer facilities, it is possible to implement full-waveform inversion by using adjoint tomography methods (Fichtner et al., 2009; Lekic and Romanowicz, 2011; Tarantola, 1984; Tromp et al., 2005).

This chapter is focused on the imaging of global-scale or, when pertinent, of very large-scale (>1000 km) lateral heterogeneities of velocity and anisotropy in the upper mantle (0–660 km depth) where the lateral resolution is the best thanks to surface waves providing an almost uniform lateral and azimuthal coverage, particularly below oceanic areas. We will discuss how tomographic imaging completely renewed our vision of upper mantle dynamics. It makes it possible to relate surface geology and plate tectonics to underlying mantle convection and to map at depth the origin of geologic objects such as continents, mountain ranges, slabs, ridges, and plumes. The goal of this chapter is not to review all contributions to this topic, but to underline the main scientific issues, to present different approaches, and to illustrate the different progress (partly subjectively) by some of my results or by other more recent models. This chapter aims to show why a major step, which takes a complete account of amplitude anomalies in the most general case and which will enable to map shorter-scale heterogeneities, is presently underway.

1.19.2 Effects of Seismic Velocity and Anisotropy on Seismograms

For theoretical and practical reasons, the Earth was considered, for a long time, as composed of isotropic and laterally homogeneous layers. While an isotropic elastic medium can be described by two independent elastic parameters (λ and μ Lamé parameters), the cubic symmetry requires three parameters, but the most commonly used anisotropic medium (transverse isotropy with vertical symmetry axis) necessitates five independent parameters (Anderson, 1961; Love, 1927) and the most general elastic medium requires 21 independent parameters. However, since the 1960s, it was recognized that most parts of the Earth are not only laterally heterogeneous but also anisotropic. Though the lateral heterogeneities of seismic velocities were used for a long time for geodynamic applications, the importance of anisotropy for understanding geodynamic processes has only been recognized recently.

Seismology is an observational field based on the exploitation of seismic recordings of the displacement (velocity or acceleration) of the Earth induced by earthquakes. Broadband three-component high dynamic-range seismometers have been installed in more than 1000 stations around the world during the last 30 years (see overview in **Chapter 1.01**). Thanks to progress in instrumentation and theoretical developments, it is now possible to observe and to take a simultaneous account of the effects of lateral heterogeneities of velocity and anisotropy on seismograms.

1.19.2.1 First-Order Perturbation Theory

The basic equation that governs the displacement $\mathbf{u}(\mathbf{r}, t)$ is the elastodynamics equation:

$$\rho_0 \frac{\mathrm{d}^2 u_i}{\mathrm{d}t^2} = \sum_j \sigma_{ij,j} + F_{\mathrm{I}i} + F_{\mathrm{E}i} \qquad [1]$$

where $F_{\mathrm{I}i}$ and $F_{\mathrm{E}i}$ represent, respectively, the whole ensemble of applied inertial and external forces (see Takeuchi and Saito, 1972; Woodhouse and Dahlen, 1978 or **Chapter 1.02** for a complete description of all terms). Generally, by neglecting the advection term, this equation is written in a simple way:

$$(\rho_0 \partial_{tt} - H_0)\mathbf{u}(\mathbf{r}, t) = \mathbf{F}(\mathbf{r}_{\mathrm{S}}, t) \qquad [2]$$

where H_0 is an integro-differential operator and $\mathbf{F}$ expresses all forces applied to the source volume in $\mathbf{r}_{\mathrm{s}}$ at time t (considered as external forces). $\mathbf{F}$ is assumed to be equal to 0 for $t<0$. In the elastic case, there is a linear relationship between σ_{ij} and the strain tensor ϵ_{kl}: $\sigma_{ij} = \sum_{kl} \Gamma_{ijkl}\epsilon_{kl}$ (+ terms related to the initial stress). Γ_{ijkl} is a fourth-order tensor, often written in its condensed form C_{ij} as a 6×6 matrix. By using the different symmetry conditions $\Gamma_{ijkl} = \Gamma_{jikl} = \Gamma_{ijlk} = \Gamma_{klij}$, the tensor $\mathbf{\Gamma}$ is shown to have 21 independent elastic moduli in the most general anisotropic medium. In an isotropic medium, this number reduces to 2, the Lamé coefficients λ and μ.

There are many ways for solving eqn [2] and to compute synthetic seismograms, but, at the global scale, the most elegant way is to determine the free oscillations (or normal modes) of the Earth. When solving for the free oscillations of the Earth, $\mathbf{F}=0$. The solution $\mathbf{u}(\mathbf{r}, t)$ of eqn [2] can be calculated for a spherically symmetrical nonrotating reference Earth model associated with the operator H_0, according to the equation

$$\rho_o \partial_{tt}\mathbf{u}(\mathbf{r}, t) = H_0\mathbf{u}(\mathbf{r}, t) \qquad [3]$$

The solution of eqn [3] is beyond the scope of this chapter and is described in **Chapter 1.02**. The eigenvalues of the operator H_0 are equal to $-\rho_0\omega_\ell^2$ where ${}_n\omega_\ell$ is the eigenfrequency characterized by two quantum numbers n and ℓ, respectively, termed radial and angular orders. The corresponding eigenfunctions ${}_n\mathbf{u}_\ell^m(\mathbf{r}, t)$ depend on three quantum numbers n, ℓ, m, where m is the azimuthal order, with the following property: $\ell \le m \le \ell$. Therefore, for a given eigenfrequency ${}_n\omega_\ell$ calculated in a spherically symmetrical Earth model, $2\ell+1$ eigenfunctions can be defined. The eigenfrequency ${}_n\omega_\ell$ is said to be degenerate, with a degree of degeneracy $2\ell+1$. There is a complete formal similarity with the calculation of the energy levels of the atom of hydrogen in quantum mechanics. The eigenfunctions ${}_n\mathbf{u}_\ell^m(\mathbf{r}, t)$ of the operator H_0 are orthogonal and normalized.

The important point is that the basis of functions ${}_n\mathbf{u}_\ell^m(\mathbf{r}, t)$ is complete. This implies that any displacement at the surface of the Earth can be expressed as a linear combination of these discrete eigenfunctions:

$$\mathbf{u}(\mathbf{r}, t) = \sum_{n,\ell,m} {}_n a_\ell^m \, {}_n\mathbf{u}_\ell^m(\mathbf{r}, t)$$

Therefore, these eigenfunctions can be used to calculate the synthetic displacement at any point $\mathbf{r}$, at time t, due to a force system $\mathbf{F}$ in the source volume and make it possible to model not only surface waves but also body waves. For a point force $\mathbf{F}$ at source point $\mathbf{r}_{\mathrm{s}}$, a step time function and its associated moment tensor $\mathbf{M}$, which is a good starting model for earthquakes, the solution of the eqn [2] is given by (Gilbert, 1971)

$$\mathbf{u}(r, t) = \sum_{n,\ell,m} {}_n\mathbf{u}_\ell^m(\mathbf{r}) \frac{(1-\cos {}_n\omega_\ell t)}{{}_n\omega_\ell^2} e^{\frac{-{}_n\omega_\ell t}{2Q}} (\mathbf{M} : {}_n\epsilon_\ell^m)\mathbf{r}_{\mathrm{s}} \qquad [4]$$

where ϵ is the deformation tensor. Since eqn [4] is linear in $\mathbf{M}$, it can be easily generalized to more complex spatial and temporal source functions and can be rewritten as

$$\mathbf{u}(\mathbf{r}, t) = \mathbf{G}(\mathbf{r}, \mathbf{r}_{\mathrm{s}}, t, t_{\mathrm{s}})\mathbf{M}(\mathbf{r}_{\mathrm{s}}, t_{\mathrm{s}})$$

where $\mathbf{G}(\mathbf{r}, \mathbf{r}_{\mathrm{s}}, t, t_{\mathrm{s}})$ is composed of the spatial derivatives of the Green operator of the medium. Normal mode theory is routinely used to calculate synthetic seismograms at long periods ($T \ge 30$ s) and Centroid moment tensor solutions (Dziewonski et al., 1981).

An example of real and synthetic seismograms is presented in **Figure 1**. However, there are still some discrepancies (usually frequency-dependent) between the observed and synthetic seismograms. The simplest way to explain the observed phase shifts (time delays) is to remove the assumption that the Earth is spherically symmetrical, that is, there are lateral heterogeneities between the source and the receiver. The next step is to characterize these lateral heterogeneities. Since the agreement between synthetic and observed seismograms is good at long periods ($T \ge 40$ s), we can reasonably infer that the amplitude of heterogeneities is small ($<10\%$). Behind the surface wavetrain, a long coda is usually observed, interpreted as scattered waves. However,

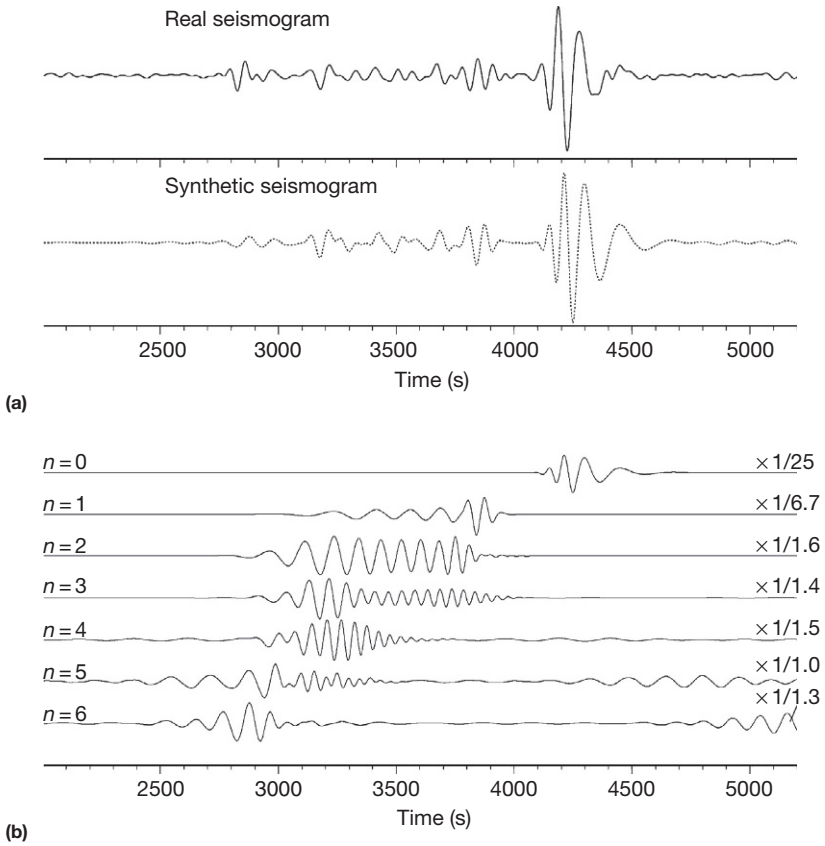

Figure 1 (a) Example of real and synthetic seismograms used for retrieving Rayleigh-wave dispersion curve for the fundamental mode and overtones (Beucler et al., 2003). Behind body waves, the signal is composed of surface waves. (b) The complex phase before the high-amplitude wave packet corresponding to the fundamental mode of Rayleigh wave ($n = 0$) can be synthetized by summing the first overtones.

when filtering out periods shorter than 40 s, this coda vanishes, which means that the scattering effect is only large in the shallowest regions of the Earth (primarily the crust and the upper lithosphere) but that it is probably negligible at larger depths. However, some groups are starting to use the information contained in these coda waves (Aki and Richards, 1980; Snieder et al., 2002) and even from ambient seismic noise (Sabra et al., 2005; Shapiro et al., 2005) for imaging the crust and lithosphere. Ambient noise tomography is a rapidly expanding field (e.g., Bensen et al., 2007) well suited to regions with dense seismic arrays and weak seismicity (see chapter by Campillo). For the sake of simplicity, this chapter is limited to long-period surface waves and it is hypothesized that the scale of lateral heterogeneities is large compared with the seismic wavelength. This point will be discussed in **Section 1.19.3.1**. A second hypothesis that must be discussed is the isotropic nature of the Earth materials. Actually, it is a poor assumption, because seismic anisotropy can be unequivocally observed at different scales. Finally, the influence of lateral variations in attenuation must also be taken into account and will be discussed elsewhere in this treatise.

1.19.2.2 Effect of Anisotropic Heterogeneities on Normal Modes and Surface Waves

Different geophysical fields are involved in the investigation of the manifestations of anisotropy of the Earth materials: mineral physics and geology for the study of the microscopic scale and seismology for scales larger than, typically, 1 km. The different observations related to anisotropy, at different scales, are reviewed in Babuska and Cara (1991), Montagner (1998), Park and Levin (2002) and in **Chapter 2.16**.

Since several decades, different kinds of observations have been used for investigating anisotropy in the upper mantle: the Rayleigh-wave and Love-wave discrepancies (Anderson, 1961), the azimuthal variation of phase velocities of surface waves (Forsyth, 1975), and the shear-wave splitting particularly for SKS waves (Silver and Chan, 1991; Vinnik et al., 1992). The lack of stations in oceanic areas explains why it is necessary to use surface waves to investigate upper mantle structure (isotropic or anisotropic) at the global or regional scales.

In the simplest case (fundamental modes, no coupling between the branches of Rayleigh and Love waves), the frequency shift $\delta\omega/\omega$ (and the corresponding phase velocity perturbation $\delta V/V$), for a constant wavenumber k, can be written by applying Rayleigh's principle (e.g., Takeuchi and Saito, 1972):

$$\left.\frac{\delta\omega}{\omega}\right|_k = \left.\frac{\delta V}{V}\right|_k = \frac{1}{2\omega}\frac{\int_\Omega \epsilon_{ij}^{*}\delta\Gamma_{ijk\ell}\epsilon_{k\ell}\,\mathrm{d}\Omega}{\int_\Omega \rho_{0n}\mathbf{u}_\ell^{m*}{}_n\mathbf{u}_\ell^{m}\,\mathrm{d}\Omega} \qquad [5]$$

where ϵ_{ij} and $\delta\Gamma_{ijkl}$ are, respectively, the second-order deformation and the deviations of the fourth-order elastic tensor

components from an SNREI (spherically symmetrical, nonrotating, elastic, and isotropic) model and ${}_n\mathbf{u}_\ell^m$ the eigenfunctions as defined in the previous section.

We only consider the propagation of surface waves in a plane-layered medium for a general slight elastic anisotropy (Montagner and Nataf, 1986), but it can be easily extended to the spherical Earth (Ekström, 2006; Larson et al., 1998; Mochizuki, 1986; Romanowicz and Snieder, 1988; Tanimoto, 1986; Trampert and Woodhouse, 2003). Smith and Dahlen (1973, 1975) found that, to the first order in anisotropy and at frequency ω, the azimuthal variation of local phase velocity (Rayleigh or Love wave) can be expanded as a Fourier series of the azimuth Ψ with only even degrees along the path and is of the form

$$\begin{aligned} V(\omega,\theta,\phi,\Psi)-V_0(\omega,\Psi)=\alpha_0(\omega,\theta,\phi)+\alpha_1(\omega,\theta,\phi)\cos 2\Psi \\ +\alpha_2(\omega,\theta,\phi)\sin 2\Psi \\ +\alpha_3(\omega,\theta,\phi)\cos 4\Psi \\ +\alpha_4(\omega,\theta,\phi)\sin 4\Psi \end{aligned} \quad [6]$$

where $V_0(\omega,\ \Psi)$ is the reference velocity of the unperturbed medium and Ψ is the azimuth along the path with respect to the north direction. Montagner and Nataf (1986) presented the expressions for the different azimuthal coefficients $\alpha_i(\omega,\theta,\phi)$ as depth integral functions dependent on 13 simple linear combinations of standard Cartesian elastic coefficients C_{ij}. Appendix shows how to relate the $3\times3\times3\times3$ tensor Γ_{ijkl} to the 6×6 matrix C_{ij} and presents detailed calculation of azimuthal terms for Love waves in the geographic coordinate system.

Constant term (0-Ψ azimuthal term: α_0):

$$\begin{aligned} A&=\rho V_{\mathrm{PH}}^2=\frac{3}{8}(C_{11}+C_{22})+\frac{1}{4}C_{12}+\frac{1}{2}C_{66}\\ C&=\rho V_{\mathrm{PV}}^2=C_{33}\\ F&=\frac{1}{2}(C_{13}+C_{23})\\ L&=\rho V_{\mathrm{SV}}^2=\frac{1}{2}(C_{44}+C_{55})\\ N&=\rho V_{\mathrm{SH}}^2=\frac{1}{8}(C_{11}+C_{22})-\frac{1}{4}C_{12}+\frac{1}{2}C_{66} \end{aligned}$$

2-Ψ azimuthal term:

$\alpha_1\cos 2\Psi$	$\alpha_2\sin 2\Psi$
$B_c=\frac{1}{2}(C_{11}-C_{22})$	$B_s=C_{16}+C_{26}$
$G_c=\frac{1}{2}(C_{55}-C_{44})$	$G_s=C_{54}$
$H_c=\frac{1}{2}(C_{13}-C_{23})$	$H_s=C_{36}$

4-Ψ azimuthal term:

$\alpha_3\cos 4\Psi$	$\alpha_3\cos 4\Psi$
$E_c=\frac{1}{8}(C_{11}+C_{22})-\frac{1}{4}C_{12}-\frac{1}{2}C_{66}$	$E_s=\frac{1}{2}(C_{16}-C_{26})$

where indices 1 and 2 refer to horizontal coordinates (1, north; 2, east) and index 3 refers to vertical coordinate. ρ is the density; V_{PH} and V_{PV} are, respectively, horizontally and vertically propagating P-wave velocities; and V_{SH} and V_{SV} are, respectively, the horizontal and vertical polarized S-wave velocities. So, the different parameters present in the different azimuthal terms are simply related to elastic moduli C_{ij}.

From a practical point of view, once source phase is removed and assuming that the scale of heterogeneities is larger than the wavelength, the total phase ϕ_t (and the travel time) between the epicenter E and the receiver R is easily related to the measurement of phase velocity $V_d(\omega)$ and therefore to the local phase velocity $V(\omega,\ \theta,\ \phi,\ \Psi)$:

$$\phi_t=\omega t_{\mathrm{E}\to\mathrm{R}}=\frac{\omega\Delta}{V_{\mathrm{d}}(\omega)}=\omega\int_{\mathrm{E}}^{\mathrm{R}}\frac{\mathrm{d}s}{V(\omega,\theta,\phi,\Psi)} \quad [7]$$

Therefore, eqns [6] and [7] define the forward problem for surface wave phase in the framework of the first-order perturbation theory and geometric optics approximation. We will see in the next section how to solve the inverse problem. That means that, ideally, surface waves in the plane case have the ability to provide information on 13 elastic parameters, which emphasizes the enormous potential of surface waves in terms of geodynamic and petrologic implications. There are only 13 elastic moduli among 21, since the propagation of surface waves is invariant against rotation by π, which corresponds to a monoclinic symmetry. The asymptotic propagation in weakly anisotropic media presented for surface waves can be extended to body waves. Jech and Psenčík (1989) demonstrated that it is similarly governed by a Fourier series in Ψ involving not only degrees zero, two, and four but also degrees one and three. Chen and Tromp (2007) expanded the approach of Jech and Psenčík and introduced eight new elastic parameters $J_{c,s}$, $K_{c,s}$, $M_{c,s}$, and $D_{c,s}$ corresponding to linear combinations of C_{ij}, respectively, describing the 1-Ψ and 3-Ψ variations.

The 0-Ψ term corresponds to the average over all azimuths and involves five independent parameters, A, C, F, L, N, which represent the equivalent transversely isotropic medium with a vertical symmetry axis (more simply named VTI or radial anisotropy). It must be noted that it is possible to retrieve the equivalent isotropic shear modulus from these five parameters. By using a Voigt average, the shear modulus μ_{iso} is equal to

$$\begin{aligned} \mu_{\mathrm{iso}}=\rho V_{\mathrm{S_{iso}}}^2=\frac{1}{15}(C_{11}+C_{22}+C_{33}-C_{12} \\ -C_{13}-C_{23}+3C_{44}+3C_{55}+3C_{66}) \end{aligned}$$

According to the expressions of A, C, F, L, N in terms of elastic moduli, $\mu_{\mathrm{iso}}=1/15(C+A-2F+6F+5N)$. So we can see that the equivalent isotropic velocity depends not only on S-wave velocities V_{SV} and V_{SH} (or radial S-anisotropy $\xi=N/L$) but also on P-wave velocities V_{PV} and V_{PH} (or radial P-anisotropy $\phi=C/A$) and on $\eta=F/(A-2L)$. By rewriting this expression $\mu_{\mathrm{iso}}=1/15(C+(1-2\eta)A+(6+4\eta)L+5N)$, neglecting anisotropy in P-wave ($\phi=1$), and assuming $\eta=1$, it is found that $\mu_{\mathrm{iso}}=\rho V_{\mathrm{S_{iso}}}^2\approx(2/3)L+(1/3)N=(2/3)\rho V_{\mathrm{SV}}^2+(1/3)\rho V_{\mathrm{SH}}^2$. Naturally, this choice is arbitrary, since, usually, there is no S-wave anisotropy without P-wave anisotropy. Another way to jointly take account of P- and S-anisotropies consists in using correlations between anisotropic parameters for petrologic models as derived by Montagner and Anderson (1989a).

The other azimuthal terms (2-Ψ and 4-Ψ) depend on four groups of two parameters, B, G, H, E, respectively, describing the azimuthal variation of A, L, F, N. These simple parameters make it possible to describe in a simple way the two seismically observable effects of anisotropy on surface waves, the so-called 'polarization' anisotropy resulting from the discrepancy between Rayleigh-wave and Love-wave dispersions (Schlue and Knopoff, 1977) and the azimuthal anisotropy first observed by Forsyth (1975) in the Nazca Plate.

Another important point in these expressions is that they provide the partial derivatives for the radial and azimuthal anisotropies of surface waves. The corresponding kernels and their depth dependence are plotted in Montagner and Nataf (1986) (**Figures 2** and **3**). These partial derivatives of the different azimuthal terms with respect to the elastic parameters can be easily calculated by using a radial anisotropic reference Earth model, such as *PREM* (Dziewonski and Anderson, 1981). The partial derivatives of the eigenperiod ${}_0T_\ell$ with respect to parameter p, $(p/T)(\partial T/\partial p)$ can easily be converted into phase velocity V partial derivatives by using

$$\frac{p}{V}\left(\frac{\partial V}{\partial p}\right)_T = -\frac{V}{U}\frac{p}{T}\left(\frac{\partial T}{\partial p}\right)_k$$

For example, the parameters G_c and G_s have the same kernel as parameter L (related to V_{SV}) as shown by comparing the expressions of R_1, R_2, and R_3 in eqn [29] of Appendix. For fundamental modes (but it is not valid for higher modes), the calculation of kernels shows that Love waves are almost insensitive to V_{SV} (**Figure 2**) and Rayleigh waves to V_{SH}. Rayleigh waves are the most sensitive to SV-waves. However, as pointed out by Anderson and Dziewonski (1982), the influence of P-waves (through parameters A and C) can be very large in an anisotropic medium. The influence of density is also very large for Love and Rayleigh waves, but as shown by Takeuchi and Saito (1972), it is largely decreased when seismic velocities are inverted for, instead of, elastic moduli and density.

1.19.2.3 Comparison Between Surface-Wave Anisotropy and SKS Splitting Data

It can be noted that some of the linear combinations of elastic moduli C_{ij}, derived from surface waves in the previous section, also come up when considering the propagation of body waves in symmetry planes for a weakly anisotropic medium (see, e.g., Crampin, 1984) and their azimuthal dependence

$$\rho V_P^2 = A + B_c\cos 2\Psi + B_s\sin 2\Psi + E_c\cos 4\Psi + E_s\sin 4\Psi$$
$$\rho V_{qSV}^2 = N - E_c\cos 4\Psi - E_s\sin 4\Psi$$
$$\rho V_{qSV}^2 = L + G_c\cos 2\Psi + G_s\sin 2\Psi$$

where V_{qSH} and V_{qSV} correspond, respectively, to quasi-SH-wave and quasi-SV-wave.

A global investigation of anisotropy inferred from SKS body wave splitting measurements (delay times and directions of maximum velocities) has been undertaken by different authors (Becker et al., 2012; Savage, 1999; Silver, 1996; Vinnik et al., 1992; Wüstefeld et al., 2009). Unfortunately, most SKS measurements have been done in continental parts of the Earth and very few in oceans. It turns out that a direct comparison of

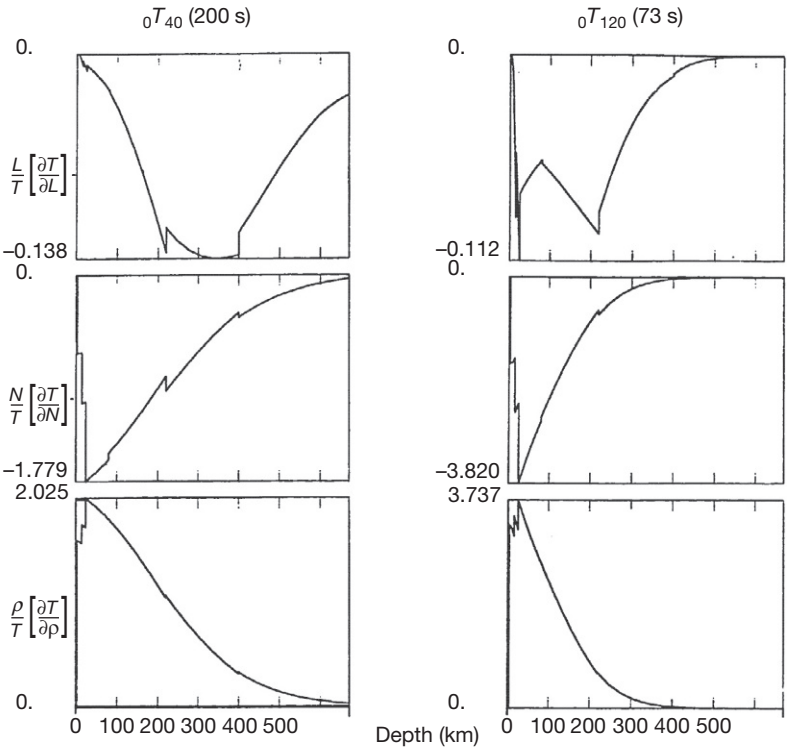

Figure 2 Partial derivatives for Love waves of the period of fundamental normal modes ${}_0T_{40}$ (left) and ${}_0T_{120}$ (right) with respect to the elastic coefficients of a transversely isotropic earth L, N, and density ρ, as a function of depth in the upper mantle. Reproduced from Montagner J-P and Nataf HC (1986) On the inversion of the azimuthal anisotropy of surface waves. *Journal of Geophysical Research* 91: 511–520. The partial derivatives with respect to A, C, F are null for these modes. The plots are normalized to their maximum amplitudes, given for a $\Delta h = 1000$ km thick perturbed layer. The combinations of elastic coefficients that have the same partial derivative as L are $-G_c$, $-G_s$ for the azimuthal terms 2-Ψ and as N are E_c, E_s for the azimuthal term 4-Ψ. Note that the amplitude of the L-partial is very small for the fundamental modes, which is not the case for higher modes.

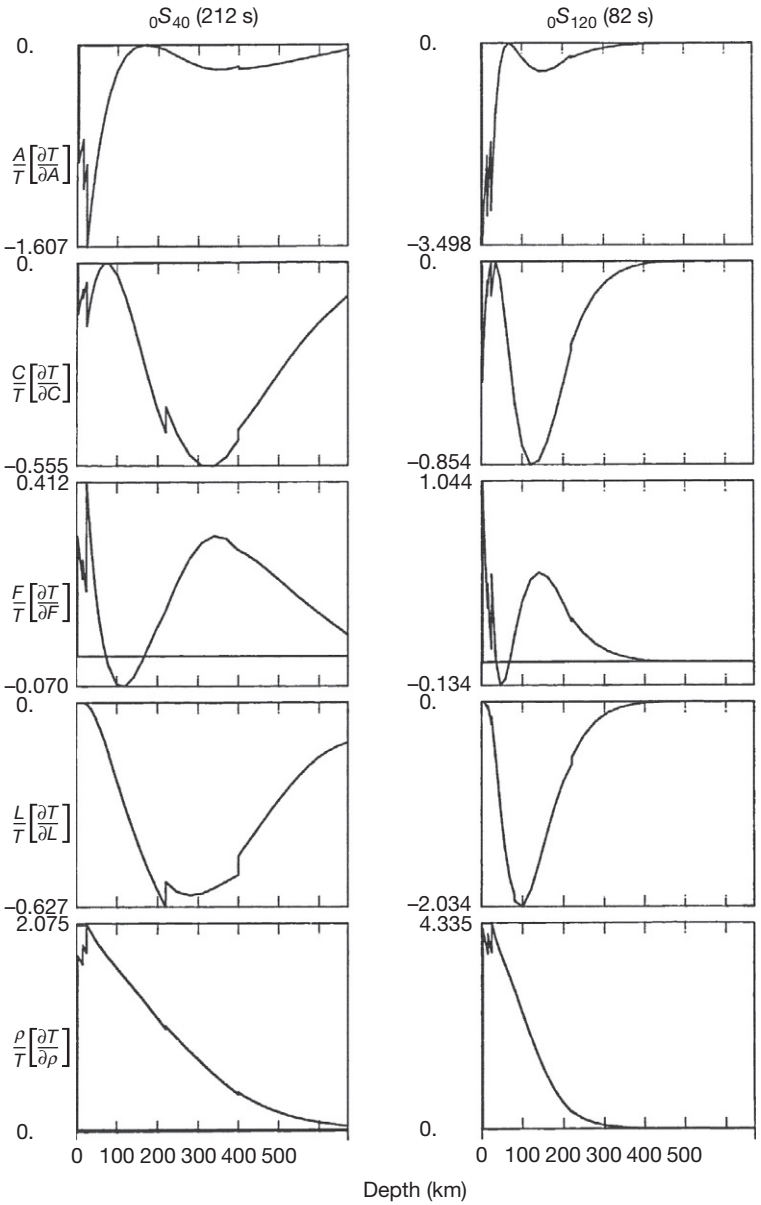

Figure 3 Kernels for Rayleigh waves. Same conventions as for **Figure 2** in the same depth range. The partial derivative with respect to N has not been plotted since its amplitude is very small for fundamental modes. Note that three partial derivatives contribute to the 2-Ψ azimuthal terms, A-partial for B_c, B_s, F-partial for H_c, H_s and the largest one L-partial for G_c, G_s.

body wave and surface wave datasets is now possible (Montagner et al., 2000). If the anisotropic medium is assumed to be characterized by a horizontal symmetry axis with any orientation (this is a very strong assumption that can be alleviated as shown by Chevrot et al. (2004), Monteiller and Chevrot (2010), and Romanowicz and Yuan (2012)) and for a vertically propagating SKS wave, a synthetic dataset of SKS delay times and azimuths can be calculated from the global distribution of anisotropy derived from surface waves, by using the following equations:

$$\delta t_{SKS} = \int_0^h dz \sqrt{\frac{\rho}{L}} \left[\frac{G_c(z)}{L(z)} \cos(2\Psi(z)) + \frac{G_s(z)}{L(z)} \sin(2\Psi(z)) \right] \quad [8]$$

where δt_{SKS} is the integrated travel time for the depth range 0–h for a propagation azimuth Ψ, where the anisotropic parameters $G_c(z)$, $G_s(z)$, and $L(z)$ are the anisotropic parameters retrieved from surface waves at different depths. It is remarkable to realize that only the G parameter (expressing the SV-wave azimuthal variation) is present in this equation. From eqn [8], we can infer the maximum value of delay time δt_{SKS}^{max} and the corresponding azimuth Ψ_{SKS}:

$$\delta t_{SKS}^{max} = \sqrt{\left\{ \int_0^h dz \sqrt{\frac{\rho}{L}} \frac{G_c(z)}{L(z)} \right\}^2 + \left\{ \int_0^h dz \sqrt{\frac{\rho}{L}} \frac{G_s(z)}{L(z)} \right\}^2} \quad [9]$$

$$\tan(2\Psi_{SKS}) = \frac{\int_0^h dz \frac{G_s(z)}{L(z)}}{\int_0^h dz \frac{G_c(z)}{L(z)}} \quad [10]$$

However, eqn [8] is approximate and only valid when the wavelength is much larger than the thickness of layers. It is based on the commutativity of anisotropic layers though the noncommutativity is present in the general calculation, as pointed out by Silver and Savage (1994) and Montagner et al. (2000). The validity of this approximation has been questioned by Silver and Long (2011) for the frequency range used in SKS studies. However, Romanowicz and Yuan (2012) demonstrated that the expressions of eqns [8]–[10] are valid for station-averaged quantities and do not depend on the order of layers and therefore that it is correct to use these expressions in joint inversions of surface waveforms and SKS station-averaged splitting measurements. It is possible to make more precise calculations by using the technique derived for two layers by Silver and Savage (1994), by using the general expressions given in Rumpker and Silver (1998) and Montagner et al. (2000), or the splitting intensity derived by Chevrot (2000). Chevrot et al. (2004) and Chevrot (2006) suggested that the use of finite-frequency kernels for SKS splitting measurements should improve the depth resolution using SKS splitting data alone.

With eqns [9] and [10], a synthetic map of the maximum value of delay time δt_{SKS}^{max} can be obtained by using a three-dimensional (3-D) anisotropic surface wave model. A detailed comparison between synthetic SKS derived from anisotropic upper mantle (AUM) (Montagner and Tanimoto, 1991) and observed SKS (Silver, 1996) was presented in Montagner et al. (2000). **Figure 4** shows an example of such a map for the Earth centered in the Pacific, by using the anisotropic surface wave model of Montagner (2002) derived from the data of Montagner and Tanimoto (1991) and Ekström et al. (1997). First of all, the comparison shows that both datasets are compatible in magnitude but not necessarily in directions. Some contradictions between measurements derived from surface waves and from body waves have been noted. The agreement of directions is correct in tectonically active areas but poor in old cratonic zones. The discrepancy in these areas results from the rapid lateral change of directions of anisotropy at a small scale. These changes stem from the complex history of these areas, which have been built by successive collages of continental pieces. It might also result from the hypothesis of horizontal symmetry axis, which was shown to be invalid in many areas (Plomerová et al., 1996). The positive consequence of this discrepancy is that a small-scale mapping of fossil anisotropy in such areas might provide clues for understanding the processes of growth of continents and mountain building opening a new field, the paleoseismology. Recently, the coherence between the predicted shear-wave splitting derived from tomographic models and actual observations of splitting has been reevaluated by using updated global compilation (Wüstefeld et al., 2009), recent tomographic models (Debayle et al., 2005; Lebedev and van der Hilst, 2008), and more sophisticated full-waveform methods to estimate synthetic splitting from tomography (Becker et al., 2012). Provided that the splitting dataset is spatially filtered to scale of tomographic models, Becker et al. (2012) found that splitting and tomography display a consistent signal that can be geodynamically interpreted (Long and Becker, 2010).

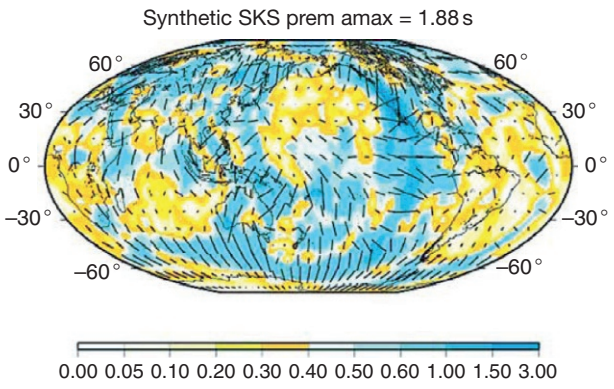

Figure 4 Map of synthetic SKS splitting derived from the anisotropic surface wave model of Montagner (2002). The delay time is expressed in seconds. Its maximum value is $A_{max} = 1.88$ s.

Unlike surface waves, SKS waves have a good lateral resolution and are sensitive to the short wavelength anisotropy just below the stations. But their drawback is that they have a poor vertical resolution. On the other hand, global anisotropic tomography derived from surface waves only provides long-wavelength anisotropy (poor lateral resolution) but enables the location at depth of anisotropy. The long-wavelength anisotropy derived from surface waves will display the same direction as the short wavelength anisotropy inferred from body waves only when large-scale vertical coherent processes are predominant. As demonstrated by Montagner et al. (2000), the best agreement between observed and synthetic SKS can be found when only layers in the uppermost 200 km of the mantle are taken into account. Moreover, tomographic models derived from surface waves lose resolution at depths >250–300 km. In some continental areas, short-scale anisotropy, the result of a complex history, might be important and even might mask the deep large-scale anisotropy more related to present convective processes leading to incompatibility between synthetic and observed splitting data. For North America, Marone and Romanowicz (2007a,b) resolved this disagreement by simultaneously inverting surface waveforms and shear-wave splitting data. They showed evidence of a layering of anisotropy with a different fast axis, which was also observed in many oceanic or continental regions. From a statistical point of view, good agreement between orientations of anisotropy and plate velocity motion is primarily found for fast-moving plates, in particular below oceans. The differences between anisotropy and tectonic plate directions are related to more complex processes, as will be seen in **Section 1.19.3**.

1.19.3 Upper Mantle Tomography of Seismic Velocity and Anisotropy

We now show how to implement the theory of **Section 1.19.1** from a practical but general point of view and how to design a tomographic technique in order to invert for the 13 different elastic parameters and density. A tomographic technique necessitates to solve simultaneously a forward problem and an inverse problem. By using the results of the previous section, it successively considers how to set the forward problem and how it is used to retrieve a set of parameters by inversion.

1.19.3.1 Forward Problem

First, it is necessary to define the data space **d** and the parameter space **p**. It is assumed that a functional **g** relating **d** and **p** can be found such that

$$\mathbf{d} = \mathbf{g}(\mathbf{p})$$

where **d** is the set of data (which samples the data space) and **p** is the set of parameters.

1.19.3.1.1 Data space: *d*

The basic dataset is made of seismograms $\mathbf{u}(t)$. We can try to directly match the waveform in the time domain, or we can work in the Fourier domain, by separating phase and amplitude on each component $u_i(t)$:

$$u_i(t) = \int_{-\infty}^{\infty} \sum_{n=0}^{\infty} A_{ni}(\omega) e^{i(\omega t - \phi_{ni})} d\omega \quad \text{or} \quad u_i(\omega) = \sum_{n=0}^{\infty} A_{ni}(\omega) e^{i\phi_{ni}(\omega)}$$

where $\Sigma_{n=0}^{\infty}$ expresses the sum over the different dispersion branches (higher modes) and $A_{ni}(\omega)$ and ϕ_{ni} (ω) are, respectively, the amplitude and the phase of the seismic waves as functions of the angular frequency ω. The most classical methods are based on ray theory. In the framework of full ray theory (e.g., Ekström et al., 1997 or Ferreira and Woodhouse, 2007), for a given path between source E and receiver R with epicentral distance Δ and a given mode n (we omit the index n in the following), the phase $\phi_i(\omega)$ is the sum of four terms:

$$\phi_i(\omega) = \phi_{Si} + \phi_{Pi} + \phi_{Ri} + \phi_{0i}$$

where ϕ_{Si} is the initial source phase, $\phi_{Pi} = \mathbf{k}_i \cdot \mathbf{r}$ the propagation phase, ϕ_{Ri} the receiver phase (including the instrumental response), and ϕ_{0i} the phase related to the number of polar phase shifts. ϕ_{Si} is correctly given by using the centroid moment tensor solution (Dziewonski et al., 1981). The amplitude A_i for a given mode n is the product of four terms:

$$A_i = A_{Si} A_{Pi} A_{Ri} A_{Qi}$$

where A_{Si} is the excitation at the source, A_{Pi} is the geometric spreading factor and might include the effects of focusing and defocusing, A_{Ri} is the receiver amplitude, and A_{Qi} is the attenuation factor along the path.

The approach consisting in fitting full seismic waveforms is more general but, from a practical point of view, it does not necessarily correspond to the simplest choice. In a heterogeneous medium, the calculation of amplitude and phase effects makes it necessary to calculate the coupling between different multiplets (Li and Tanimoto, 1993; Li and Romanowicz, 1995; Marquering et al., 1996), which is very time-consuming. When working in the Fourier domain, different time windows can be considered and the phase of different seismic trains, body waves, and surface waves can be separately matched (Debayle and Ricard, 2012; Lebedev and van der Hilst, 2008; Lévêque et al., 1991; Nolet, 1990) under drastic simplifying assumptions. **Figure 1** showed an example of observed and synthetic seismograms, the latter obtained by normal mode summation with the different higher modes. The fundamental wavetrain $(n = 0)$ is well separated from other modes at large epicentral distances. The part of the seismogram corresponding to higher modes $(n > 0)$ is more complex and shows overlap of these modes in the time domain. Therefore, from a practical point of view, the fitting of the fundamental-mode wavetrain will not cause any problem and has been widely used in global mantle tomography.

The use of higher-mode wavetrains and the separation of overtones are much more difficult. The first attempts were performed by Nolet (1975), Cara (1979), Okal and Jo (1985), and Dost (1990) by applying a spatial filtering method. Unfortunately, all these techniques can only be applied in areas where dense arrays of seismic stations are present, that is, in North America and Europe. By using a set of seismograms recorded at one station but corresponding to several earthquakes located in a small source area, Stutzmann and Montagner (1994) showed how to separate the different higher modes. A similar approach was also followed by Van Heijst and Woodhouse (1997) and more recently by Visser et al. (2008). We only detail in this chapter the classical technique that was designed for fitting the fundamental-mode wavetrain and the reader is referred to Stutzmann and Montagner (1994), Van Heijst and Woodhouse (1997), Beucler et al. (2003), and Visser et al. (2008) for the description of the recovery of higher-mode dispersion properties and to Romanowicz (2002) for a general overview. **Figure 5** presents an example of phase velocity dispersion for different surface wave modes (fundamental and first higher modes (Beucler et al., 2003)) and how they compare with previous investigations (Cara, 1979; Van Heijst and Woodhouse, 1997).

We take advantage of the fact that, according to Fermat's principle, the phase velocity perturbation is only dependent to the second order on path deviations, whereas amplitude perturbations are dependent, to the first order, on these deviations, which implies that the eigenfunctions must be recalculated at each iteration. Therefore, the phase is a more robustly observable than the amplitude. The amplitude $A(\omega)$ depends in a complex manner on seismic moment tensor, attenuation, scattering, focusing effects, station calibration, and near-receiver structure, whereas the contribution of lateral heterogeneities of seismic velocity and anisotropic parameters to the phase $\phi(\omega)$ can be easily extracted. The dataset under investigation is composed of propagation times (or phase velocity measurements for surface waves) along paths $\mathbf{d} = \{\Delta / V_{\text{obs}}(\omega)\}$.

The phase of a seismogram at time t is decomposed as follows: $\phi = \mathbf{k} \cdot \mathbf{r} + \phi'_0$, where ϕ' is the initial phase including several terms detailed previously. ϕ can be measured on seismograms by Fourier transform. We usually assume that ϕ_S is correctly given by the centroid moment tensor solution. For a path between epicenter E and receiver R with an epicentral distance Δ, the phase ϕ is given by

$$\phi = \frac{\omega \Delta}{V_{\text{obs}}} + \phi'_0 \qquad [11]$$

In the general case, we want to relate the observed phase velocity $V_{\text{obs}}(\omega)$ to the parameters of the Earth model $\mathbf{p}(\mathbf{r}, \theta, \phi)$. Data and 3-D parameters can be related through integrals over the whole volume of the Earth. But for computing reasons, it is usual to use a multistep approach, where we first retrieve the local phase velocity $V(\omega, \theta, \phi, \Psi)$ including its azimuthal terms (as a function of the azimuth Ψ), and then perform the inversion at depth. These two steps can be reversed

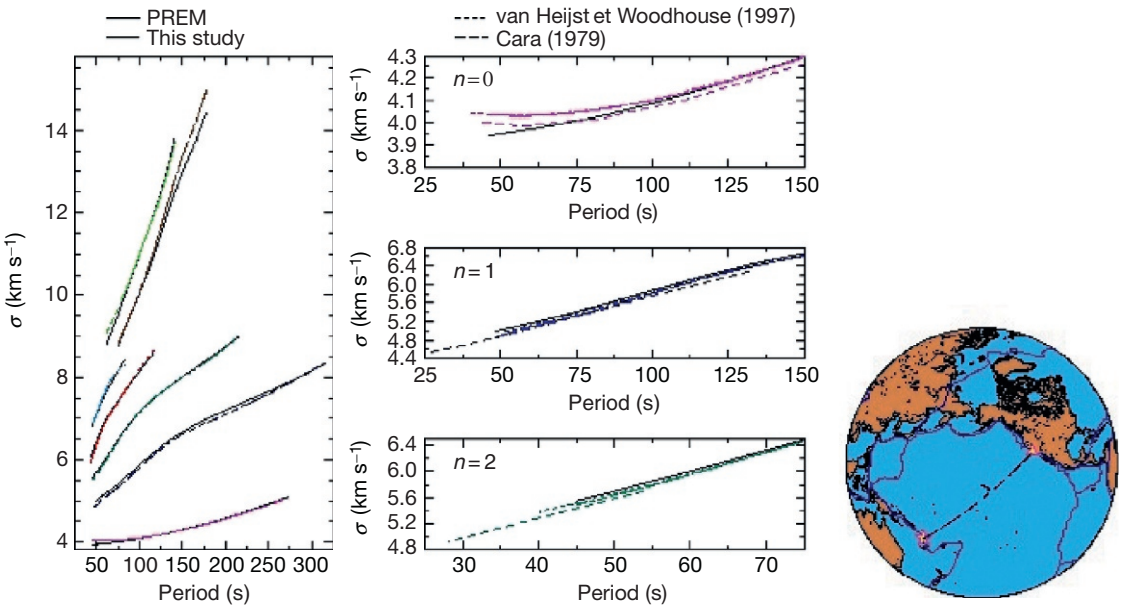

Figure 5 Phase velocity of the fundamental mode and the first six higher modes of Rayleigh compared with PREM (right plot) and with results (center) obtained in previous studies along the same path between Vanuatu and California (SCZ GEOSCOPE station). Reproduced from Beucler E, Stutzmann E, and Montagner J-P (2003) Measuring surface wave higher mode velocities by the roller coaster algorithm. *Geophysical Journal International* 155: 289–307.

since the order of the integrations can be reversed as done, for example, by Nolet (1990) or Lévêque et al. (1991). It is necessary to consider the nature of the perturbed medium. Following the approach of Snieder (1988), if the perturbed medium is at the same time smooth (long-wavelength heterogeneities) and weak (small amplitude of heterogeneities), the geometric optics approximation (and ray theory) applies. This hypothesis is not necessarily met within the Earth where some geologic objects (slabs, mantle plumes, etc.) have a length scale that can be close to the seismic wavelength. In the approximation of ray theory, the volume integral reduces to the curvilinear integral along the geometric ray path. When ray theory is applicable,

$$\phi - \phi_0' = \frac{\omega \Delta}{V_{\text{obs}}(\omega)} \int_{\text{E}}^{\text{R}} \frac{\omega \, \text{d}s}{V(\omega, \theta, \phi, \Psi)} \qquad [12]$$

where the integral is evaluated along the ray path between the epicenter E and the receiver R. Following the results of the previous section, different approximations are implicitly made when using this expression of the phase:

- Large angular order $\ell \gg 1$, but not too large (scattering problems): From a practical point of view, this means that measurements are performed in the period range $40\,\text{s} < T < 200\,\text{s}$ with seismic wavelengths between 200 and 1000 km.
- Geometric optics approximation: If λ is the wavelength of the surface wave at period T and Λ_S the spatial wavelength of heterogeneity $\Lambda_S \gg \lambda = VT \Rightarrow \Lambda S \gtrsim 2000\,\text{km}$, epicentral distance Δ must be larger than seismic wavelength.
- Slight anisotropy and heterogeneity $\delta V/\text{x}V \ll 1$: According to Smith and Dahlen (1973) for the plane case, the local phase velocity can be decomposed as a Fourier series of the azimuth Ψ (eqn [6]).

Each azimuthal term $\alpha_i(T, \theta, \phi)$ of eqn [6] can be related to the set of parameters $p_i(r, \theta, \phi)$ (density + 13 elastic parameters), according to the expressions derived in Appendix:

$$\frac{\Delta}{V_{\text{obs}}(T)} - \frac{\Delta}{V_0(T)} = \sum_{j=0}^{2} \sum_{i=1}^{14} \int_{\text{E}}^{\text{R}} \frac{\text{d}s}{V_0} \int_0^a \left[\left(\frac{p_i}{V} \frac{\partial V}{\partial p_i} \right)_j \frac{\delta p_i(r, \theta, \phi)}{p_i} \cos(2j\Psi) + \left(\frac{p_i}{V} \frac{\partial V}{\partial p_i} \right)_j \frac{\delta p_i(r, \theta, \phi)}{p_i} \sin(2j\Psi) \right] \frac{\text{d}z}{\Delta h} \qquad [13]$$

Equation [13] defines the forward problem in the framework of first-order perturbation theory, relating the data and the parameter spaces. This approach is usually named PAVA (path average approximation). Many terms in eqn [13] are equal to zero since all parameters are not present in each azimuthal term. A last important ingredient in the inverse problem formulation is the 'structure' of the data space. It is expressed through its covariance function (continuous case) or covariance matrix (discrete case) of data $\mathbf{C_d}$. When data d_i are independent, $\mathbf{C_d}$ is diagonal and its elements are the square of the errors on data σ_{di}.

1.19.3.1.2 Finite-frequency effects

The ray-based tomographic approach (e.g., Debayle et al., 2005; Debayle and Ricard, 2012; Ferreira et al., 2010; Kustowski et al., 2008a,b; Lebedev and van der Hilst, 2008; Ritsema et al., 2011) has reached its theoretical resolution limit ($\approx$1000 km), and it is necessary to move to full-waveform inversion in order to solve spatial wavelengths of the order of magnitude of seismic wavelength. As mentioned previously, a strong hypothesis is that in the framework of geometric optics approximation, only large-scale heterogeneities can be

retrieved. But interesting geologic objects such as slabs and plumes are smaller-scale. To go beyond the ray theory, it is necessary to take account of the finite-frequency effect when scale length has the same order of magnitude as the seismic wavelength. It is possible to use the scattering theory based on the Born or Rytov approximations (see, e.g., Woodhouse and Girnius (1982) for normal mode approach, Snieder (1988) for surfaces waves, and Dahlen et al. (2000 and Yomogida (1992) for body waves). Equation [13] shows that the sensitivity kernels are 1-D, meaning that only heterogeneities in the vertical plane containing the source and the receiver are taken into account, whereas, by using the scattering theory, it is possible to calculate 3-D kernels and consequently to take account of off-path heterogeneities. Equations [12] and [13] must be replaced by an integral over the volume Ω:

$$\frac{\Delta}{V_{\mathrm{obs}}(T)}-\frac{\Delta}{V_0(T)}=\sum_{i=1}^{21}\iiint_{\Omega}K_i(T,\theta,\phi,\Psi)\frac{\delta p_i(r,\theta,\phi)}{p_i}\mathrm{d}\Omega \quad [14]$$

where $K(T, \theta, \phi, \Psi)$ is the scattering Fréchet sensitivity kernel, extended to the 21 components of the elastic tensor, which depends on wave type (body waves or Rayleigh or Love surface waves) and on the relative location of E and R (see, e.g., Romanowicz, 2002, for a review). In the framework of ray theory, $K(T, \theta, \phi, \Psi)$ is zero except along the ray. Very different strategies can be followed for calculating this triple integral, by separating the surface integral and the radial integral. For a point scatterer, the kernel displays a typical shape of banana doughnut (Dahlen et al., 2000). Different approximations of $K(T, \theta, \phi, \Psi)$ have been proposed (Ritzwoller et al., 2002; Spetzler et al., 2002; Yoshizawa and Kennett, 2002), but Sieminski et al. (2004) claimed that ray theory surface wave tomography with a very dense path coverage can detect heterogeneities with length scales close and even smaller than the seismic wavelength. The discussion of the advantages and shortcomings of these different techniques is beyond the scope of this chapter, but some new tomographic models using 3-D sensitivity kernels are constructed (Zhou et al., 2004, 2006) for radially anisotropic media. With the explosion of computational infrastructure, it is possible to go beyond approximate asymptotic methods for the calculation of travel times and synthetic seismograms, by using modern numerical methods such as spectral element method (Komatitsch and Vilotte, 1998; Komatitsch and Tromp, 1999) and adjoint tomographic techniques (Fichtner et al., 2009; Tape et al., 2009; Tarantola, 1984; Tromp et al., 2005). A new revolution in seismic tomography is ongoing in using adjoint tomography, and first accurate images at the global scale (Lekic and Romanowicz, 2011) and at the regional scale of Europe (Zhu et al., 2012) should shed new light on the deep structure of the mantle.

1.19.3.1.3 Parameter space: *p(r)*

It is quite important to consider the structure of the parameter space in detail. First of all, it is necessary to define which parameters are required to explain our dataset and how many physical parameters can be effectively inverted for in the framework of the theory that is considered. For example, if the Earth is assumed to be elastic, laterally heterogeneous but isotropic, only three independent physical parameters, V_P, V_S, and density ρ (or the elastic moduli λ, μ, and ρ), can be inverted for from surface waves. In a transversely isotropic medium with a vertical symmetry axis (Anderson, 1961; Takeuchi and Saito, 1972), the number of independent physical parameters is now 6 (five elastic parameters + density). In the most general case of a weak anisotropy, 14 physical parameters (13 combinations of elastic moduli + density) can actually be inverted for using surface waves. When using the full-waveform inversion, the whole elastic tensor (21 parameters) can be, in theory, inverted for. Therefore, the number of 'physical' parameters p_i depends on the underlying theory, which is used for explaining the dataset.

Once the number of 'physical' independent parameters is defined, we must define how many spatial (or geographic) parameters are required to describe the 3-D distributions $p_i(r, \theta, \phi)$. That is a difficult problem because the number of 'spatial' parameters that can be reliably retrieved from the dataset is not necessarily sufficient to provide a correct description of $p_i(r, \theta, \phi)$, that is, of the real Earth. The correct description of $p_i(r, \theta, \phi)$ depends on its spectral content: For example, if $p_i(r, \theta, \phi)$ is characterized by very large wavelengths, only a small number of spatial parameters are necessary, but if $p_i(r, \theta, \phi)$ presents very small-scale features, the number of spatial parameters will be very large. In any case, it is necessary to assess the range of possible variations for $p_i(r, \theta, \phi)$ in order to provide some bounds on the parameter space. This is done through a covariance function of parameters in the continuous case (or a covariance matrix for the discrete case) $\mathbf{C}_{p_i p_j}(\mathbf{r}, \mathbf{r}')$ at two different points $\mathbf{r}$, $\mathbf{r}'$. These a priori constraints can be provided by other fields in geosciences, geology, mineralogy, numerical modeling, etc.

Consequently, a tomographic technique must not be restricted to the inversion of parameters $\mathbf{p} = \{p_i(r, \theta, \phi)\}$ that are searched for, but must include the calculation of the final covariance function (or matrix) of parameters $\mathbf{C_p}$. That means that the retrieval of parameters is contingent on the resolution and the errors of the final parameters and is largely dependent on the resolving power of data (Backus and Gilbert, 1967, 1968, 1970). Finally, the functional $\mathbf{g}$, which expresses the theory relating the data space to the parameter space, is also subject to uncertainty. In order to be completely consistent, it is necessary to define the domain of validity of the theory and to assess the error σ_T associated with the theory. Tarantola and Valette (1982) showed that the error σ_T is simply added to the error on data σ_d.

1.19.3.2 Inverse Problem

So far, we did not make any assumptions on the functional $\mathbf{g}$ relating data and parameters. But in the framework of ray theory and of first-order perturbation theory, the forward problem is usually linearized and eqn [13] can be simply written in the linear case as

$$\mathbf{d} = \mathbf{G}\mathbf{p}$$

where $\mathbf{G}$ is now a matrix (or a linear operator) composed of Fréchet derivatives of $\mathbf{d}$ with respect to $\mathbf{p}$, which has the dimensions $n_d \times n_p$ (number of data × number of parameters). This matrix usually is not square and many different techniques in

the past have been used for inverting $\mathbf{G}$. In any case, the inverse problem will consist in finding an inverse for the functional $\mathbf{g}$ that we will write $\tilde{\mathbf{g}}^{-1}$, notwithstanding the way it is obtained, such that

$$\mathbf{p} = \tilde{\mathbf{g}}^{-1}(\mathbf{d})$$

To solve the inverse problem, different algorithms can be used. The least-squares solution is usually solved by minimizing a cost function J. Making symmetrical the data space and the parameter space, Tarantola and Valette (1982) defined the cost function J as

$$J = (\mathbf{d} - \mathbf{Gp})^t \mathbf{C}_\mathbf{d}^{-1}(\mathbf{d} - \mathbf{Gp}) + (\mathbf{p} - \mathbf{p}_0)^t \mathbf{C}\mathbf{p}^{-1}(\mathbf{p} - \mathbf{p}_0)$$

The first term corresponds to classical least squares with no damping, whereas the second term corresponds to norm damping, which imposes smoothness upon the parameter space. Different choices were proposed for this second term. For example, Montagner (1986b) used a Gaussian covariance function characterized by a correlation length and an a priori error σ_p on parameters, whereas Su et al. (1984) preferred to minimize the roughness of the model. Other choices consist in taking a constant value such that $\delta\mathbf{p}^t\mathbf{C}_\mathbf{p}^{-1}\delta\mathbf{p} = \lambda^2\delta\mathbf{p}^t\delta\mathbf{p}$ (Yoshizawa and Kennett, 2004). Or the covariance operator can be replaced by a Laplacian operator (see, e.g., Zhou et al., 2006):

$$\delta\mathbf{p}^t\mathbf{C}_\mathbf{p}^{-1}\delta\mathbf{p} = \epsilon\left(\iiint\left|\nabla^2\left(\frac{\delta p}{p}\right)\right|^2 \mathrm{d}\Omega\right)^{1/2}$$

A discussion about damping can be found in Trampert and Snieder (1996) who prefer Laplacian over model damping to reduce the spectral leakage. As an example, by using the expression of J, a quite general and widely used algorithm has been derived by Tarantola and Valette (1982):

$$\begin{aligned}\mathbf{p} - \mathbf{p}_0 &= \left(\mathbf{G}^t\mathbf{C}_\mathbf{d}^{-1}\mathbf{G} + \mathbf{C}_{\mathbf{p}0}^{-1}\right)^{-1}\mathbf{G}^t\mathbf{C}_\mathbf{d}^{-1}(\mathbf{d} - \mathbf{g}(\mathbf{p}) + \mathbf{G}(\mathbf{p} - \mathbf{p}_0)) \\ &= \mathbf{C}_{\mathbf{p}0}\mathbf{G}^t\left(\mathbf{C}_\mathbf{d} + \mathbf{G}\mathbf{C}_{\mathbf{p}0}\mathbf{G}^t\right)^{-1}(\mathbf{d} - \mathbf{g}(\mathbf{p}) + \mathbf{G}(\mathbf{p} - \mathbf{p}_0))\end{aligned} \quad [15]$$

where $\mathbf{C}_\mathbf{d}$ is the covariance matrix of data, $\mathbf{C}_{\mathbf{p}0}$ is the covariance function of parameters $\mathbf{p}$, and $\mathbf{G}$ is the Fréchet derivative of the operator $\mathbf{g}$ at point $\mathbf{p}(\mathbf{r})$. This algorithm can be made more explicit by writing it in its integral form:

$$\mathbf{p}(\mathbf{r}) = \mathbf{p}_0(\mathbf{r}) + \sum_{i=1}^{n_\mathrm{d}}\sum_{j=1}^{n_\mathrm{d}}\int_V \mathrm{d}\mathbf{r}' C_{p0}(\mathbf{r}, \mathbf{r}')G_i(\mathbf{r}')\left(S^{-1}\right)_{ij}F_j \quad [16]$$

where n_d is the number of data, $S_{ij} = C_{dij} + \int_V \mathrm{d}\mathbf{r}_1 \int_V \mathrm{d}\mathbf{r}_2\ G_i(\mathbf{r}_1)\ C_{P0}\ (\mathbf{r}_1,\ \mathbf{r}_2)G_j(\mathbf{r}_2)$, and $F_j = d_j - g_j(\mathbf{p}) + \int_V \mathrm{d}\mathbf{r}''\ G_j(\mathbf{r}'')(\mathbf{p}(\mathbf{r}'') - \mathbf{p}_0(\mathbf{r}''))$. S_{ij} is the matrix expressing the interaction between propagating waves for data i and j. In the framework of ray theory, the double integral in S_{ij} is replaced by a double integral along ray paths i and j, which is only significantly different from zero at the crossing points of both paths (Montagner and Tanimoto, 1990).

This algorithm can be iterated and is suited for solving slightly nonlinear problems. Different strategies can be followed to invert for the 3-D models $\mathbf{p}(\mathbf{r})$, because the size of the inverse problem is usually enormous in practical applications and a compromise must be found between resolution and accuracy (and also computing time). For the example of mantle tomography, a minimum parameter space will be composed of 13 (+density) physical parameters multiplied by 30 layers (if the mantle is divided into 30 independent layers). If geographic distributions of parameters are searched for up to degree 40 (lateral resolution around 1000 km), that implies a number of about 700 000 independent parameters. Such a problem is still very hard to handle from a computational point of view. A simple approach for solving this problem consists in dividing the inversion procedure into two steps. The first step consists in regionalizing phase (or group) velocity data in order to retrieve the different azimuthal terms, and the second step is the inversion at depth. It was implemented by Montagner (1986a,b) and a very similar technique is presented by Barmin et al. (2001). In case of a large dataset, Montagner and Tanimoto (1990) showed how to handle the inverse problem by making a series expansion of the inverse of matrix S. It was recently optimized from a computational point of view by Debayle and Sambridge (2004) and Beucler and Montagner (2006). One advantage of this technique is that it can be applied equally well to regional studies or global studies. In case of imperfect spatial coverage of the area under investigation, it does not display ringing phenomena commonly observed when a spherical harmonics expansion is used (Tanimoto, 1986).

From a practical point of view, the choice of the model parameterization is also very important and different possibilities can be considered:

- Discrete basis of functions:

A simple choice consists in dividing the earth into 3-D blocks with a surface block size different from the radial one. The size of block depends on the lateral resolution expected from the path coverage. A variant of this parameterization is the use of a set of spherical triangular grid points (see, e.g., Zhou et al., 2006). The block decomposition is valid as well for global investigations as for regional studies. Usually, the Earth surface parameterization is different for the radial one. For global study, the natural basis is composed of the spherical harmonics for the horizontal variations $p_i(r, \theta, \phi) = \sum_{\ell=0}^{\ell_\mathrm{max}}\sum_{m=-\ell}^{\ell} a_\ell^m(r)Y_\ell^m(\theta, \phi)$. Other choices are possible, such as spherical splines (Wang and Dahlen, 1995). When data coverage is very uneven, other strategies are proposed using irregular cells or adaptive meshes (see, e.g., Zhang and Thurber, 2005 and **Chapter 1.10**).

- Continuous function $\mathbf{p}(\mathbf{r})$:

In this case, the function is directly inverted for. Since the number of parameters is then infinite, it is necessary to regularize the solution by defining a covariance function of parameters $C_{p0}(\mathbf{r},\ \mathbf{r}')$. For the horizontal variations, a von Mises distribution (Montagner, 1986b) can be used for initial parameters $\mathbf{p}_0(\mathbf{r})$:

$$C_{p0}(\mathbf{r}, \mathbf{r}') = \sigma_p(\mathbf{r})\sigma_p(\mathbf{r}')\exp\frac{\cos\Delta_{\mathbf{r}\mathbf{r}'} - 1}{L_\mathrm{cor}^2} \approx \sigma_p(\mathbf{r})\sigma_p(\mathbf{r}')\exp\frac{-\Delta_{\mathbf{r}\mathbf{r}'}^2}{2L_\mathrm{cor}^2}$$

where L_cor is the correlation length that defines the smoothness of the final model. This kind of distribution is well suited for studies on a sphere and is asymptotically equivalent to a Gaussian distribution when $L_\mathrm{cor} \ll a$ (a radius of the Earth). When different azimuthal term distributions are searched for,

it is possible to define cross-correlated covariance functions of parameters $C_{pipj}(\mathbf{r}, \mathbf{r}')$, but since the different terms of the Fourier expansion in azimuth correspond to orthogonal functions, the cross-correlated terms off-diagonal can be taken equal to zero.

It is interesting to note that in eqn [16], the Fréchet derivatives G along the path are multiplied by the Gaussian covariance operator C_{p0}. It means that the technique, which can be named 'Gaussian' tomography, is equivalent to use 'fat' rays: When the correlation length is wider than the Fresnel zone, ray theory applies, and consequently, the finite-frequency effects can be neglected. As discussed by Ritzwoller et al. (2002) and Sieminski et al. (2004), there might be some slight differences in amplitude between Gaussian tomography and diffraction tomography (taking account of finite-frequency effects), but not in the location of heterogeneities provided that the spatial path coverage is sufficiently dense. The radial parameterization must be related to the resolving capability of the data at depth, according to the frequency range under consideration. For the radial variations, polynomial expansions can be used (see, e.g., Dziewonski and Woodhouse (1987) for Chebyshev polynomials or Boschi and Ekström (2002) for radial cubic splines). Since the number of physical parameters is very large for the inversion at depth, physical parameters are usually correlated. The different terms of the covariance function C_p between parameters p_1 and p_2 at radii r_i and r_j can be defined as follows:

$$C_{p1,p2}(r_i, r_j) = \sigma_{p1}(r_i)\sigma_{p2}(r_j)\zeta_{p1,p2}\exp -\frac{(r_i - r_j)^2}{2L_{ri}L_{rj}}$$

where $\zeta_{p1,p2}$ is the correlation between physical parameters p_1 and p_2 inferred, for instance, from different petrologic models (Montagner and Anderson, 1989a) such as pyrolite (Ringwood, 1975) and piclogite (Anderson and Bass, 1984; Bass and Anderson, 1984). L_{ri}, L_{rj} are the radial correlation lengths that are used to smooth the inverse model.

The a posteriori covariance function is given by

$$\begin{aligned} C_p &= C_{p0} - C_{p0}G^{\mathrm{T}}\left(C_d + GC_{p0}G^{\mathrm{T}}\right)^{-1}GC_{p0} \\ &= \left(G^T C_d^{-1} G + C_{p0}^{-1}\right)^{-1} \end{aligned} \quad [17]$$

The resolution R of parameters can be calculated as well. It corresponds to the impulsive response of the system $\mathbf{p} = \tilde{\mathbf{g}}^{-1}\mathbf{d} = \tilde{\mathbf{g}}^{-1}\mathbf{g}\mathbf{p}' = R\mathbf{p}'$. If the inverse problem is perfectly solved, R is the identity function or matrix. However, the following expression of resolution is only valid in the linear case (Montagner and Jobert, 1981) inasmuch as the theory is accurate enough:

$$\begin{aligned} R &= C_{p0}G^{\mathrm{T}}\left(C_d + GC_{p0}G^{\mathrm{T}}\right)^{-1}G \\ &= \left(G^{\mathrm{T}}C_dG + C_{p0}\right)^{-1}G^{\mathrm{T}}C_d^{-1}G \end{aligned} \quad [18]$$

It is interesting to note that the local resolution of parameters is imposed by both the correlation length and the path coverage, unlike the Backus and Gilbert (1967, 1968) approach, which primarily depends on the path coverage. The effect of a damping factor in the algorithm to smooth the solution is equivalent to the introduction of a simple covariance function on parameters weighted by the errors on data (Ho-Liu et al., 1989). When the correlation length chosen is very small, the algorithms of Backus and Gilbert (1968, 1970) and Tarantola and Valette (1982) are equivalent.

By considering the a posteriori covariance function and the resolution, it is possible to assess the reliability of the hypotheses made about the independence of parameters. For example, Tanimoto and Anderson (1985) and Montagner and Jobert (1988) showed that there is a trade-off between azimuthal terms and constant terms in the case of a poor azimuthal coverage. For the inversion at depth, Nataf et al. (1986) also displayed the trade-off between physical parameters V_{PH}, V_{SV}, ξ, ϕ, and η when only Rayleigh and Love wave 0-Ψ terms are used in the inversion process.

Though 13 elastic parameters (+density) are necessary to explain surface wave data (Rayleigh and Love waves), only four parameters are well resolved for small anisotropy (Montagner and Jobert, 1988): the azimuthally averaged S-wave velocity V_S, the radial anisotropy expressed through the ξ parameter ($\xi = (V_{SH}/V_{SV})^2$) where V_{SH} (resp. V_{SV}) is the velocity of S-wave propagating horizontally with horizontal transverse polarization (resp. with vertical polarization), and the $\mathbf{G}$ (G_c, G_s) parameters expressing the horizontal azimuthal variation of V_{SV}. ξ was introduced in the reference Earth model PREM (Dziewonski and Anderson, 1981) down to 220 km in order to explain a large dataset of free oscillation eigenfrequencies and body wave travel times. The other elastic parameters can be derived, by using constraints from petrology in order to reduce the parameter space (Montagner and Anderson, 1989a). This approach was followed by Montagner and Anderson (1989b) to derive an average reference earth model and by Montagner and Tanimoto (1991) for the first global 3-D anisotropic model of the upper mantle.

1.19.3.3 Isotropic and Anisotropic Images of the Upper Mantle

The complete anisotropic tomographic procedure has been implemented for making different regional and global studies. Many global isotropic tomographic models of the upper mantle were published since Wooodhouse and Dziewonski (1984) and the recent results have been reviewed by Romanowicz (2003) and in **Chapter 1.10**. Many models inverting only for radial anisotropy but neglecting azimuthal anisotropy have also been published (Ekström and Dziewonski, 1998; Gung et al., 2003; Kustowski et al., 2008a,b; Lebedev and van der Hilst, 2008; Lekic and Romanowicz, 2011; Nataf et al., 1984, 1986; Panning and Romanowicz, 2006; Shapiro and Ritzwoller, 2002; Zhou et al., 2006). The complete anisotropic tomographic technique (including azimuthal anisotropy) has been applied for investigating the upper mantle structure either at a regional scale or at a global scale. The number of regional investigations using surface waves is too large to cite all of them, but we give some examples of anisotropic tomographies for different regions such as the Indian Ocean (Debayle and Lévêque, 1997; Montagner, 1986a; Montagner and Jobert, 1988), the Atlantic Ocean (Mocquet and Romanowicz, 1989; Silveira and Stutzmann, 2001; Silveira et al., 1998), Africa (Debayle et al., 2001; Hadiouche et al., 1989; Montagner et al., 2007; Priestley et al., 2008; Sebai et al., 2006; Sicilia et al., 2008), the Pacific Ocean (Bussy et al., 1993; Ekström and Dziewonski, 1998; Isse et al., 2010; Montagner, 2002;

Maggi et al., 2006; Nishimura and Forsyth, 1989; Ritzwoller et al., 2004), Antarctica (Roult et al., 1994), Australia (Debayle and Kennett, 2000; Fishwick et al., 2008; Simons et al., 2002), North America (Deschamps et al., 2008; Li et al., 2003; Lin et al., 2010; Marone and Romanowicz, 2007a,b; Yuan and Romanowicz, 2010; Yuan et al., 2011), and Central Asia (Griot et al., 1998a,b; Lebedev and Nolet, 2003; Villaseñor et al., 2001; Yao et al., 2010). At a global scale, the reader is referred to the anisotropic models Montagner and Tanimoto (1991), Montagner (2002), and Debayle et al. (2005) and for a quantitative comparison of tomographic and geodynamic models to Becker and Boschi (2002) and Becker et al. (2007).

An important issue, when constructing tomographic models, is the correction for crustal structure, where sedimentary thickness and Moho depth variations are so strong that they affect dispersion of surface waves at least up to 100 s: It has been shown (Montagner and Jobert, 1988) that standard perturbation theory is inadequate to correct for crustal correction and more rigorous approaches were proposed (Boschi and Ekström, 2002; Kustowski et al., 2008a; Li and Romanowicz, 1996; Marone and Romanowicz, 2007b; Zhou et al., 2004) using the updated crustal models 3SMAC (Nataf and Ricard, 1996; Ricard et al., 1996) or CRUST2.0 (Laske et al., 2001; Mooney et al., 1998). However, even these improved crustal models are imperfect and can bias the global radial anisotropic models (Bozdağ and Trampert, 2007; Ferreira et al., 2010). An elegant way to get rid of the strong influence of the crust might be through the use of homogenization methods (Capdeville and Marigo, 2007; Capdeville et al., 2010; Lekic and Romanowicz, 2011).

As an example of the results obtained after the first step of the tomographic procedure, **Figure 6** shows different maps of 2-Ψ azimuthal anisotropy for Rayleigh waves at 100 s period for the first three modes, $n=0$, 1, 2 superimposed on the isotropic part (0-Ψ term) of phase velocity (Beucler and Montagner, 2006). From petrologic and mineralogical considerations, Montagner and Nataf (1988) and Montagner and Anderson (1989a,b) showed that the predominant terms of phase velocity azimuthal expansion are the 0-Ψ and 2-Ψ for Rayleigh waves and 0-Ψ and 4-Ψ for Love waves. However, Trampert and Woodhouse (2003) carefully addressed the requirement of azimuthal anisotropy and demonstrated that Rayleigh-wave data need both 2-Ψ and 4-Ψ terms, which is also confirmed by Beucler and Montagner (2006), but Ekström (2011) still concluded that Rayleigh-wave data only constrain the 0-Ψ and 2-Ψ terms and Love-wave data the isotropic 0-Ψ term. It was shown that for the same variance reduction, a global parameterization of anisotropy including azimuthal anisotropy requires fewer parameters than an isotropic parameterization (Montagner and Jobert, 1988). This apparent paradox can be explained by the fact that the increase of physical parameters is largely compensated by the smaller number of geographic parameters, that is, larger-scale heterogeneities. Other tests have questioned whether phase data are sensitive enough to detect azimuthal anisotropy and the use of additional polarization data has been proposed (Larson et al., 1998; Laske and Masters, 1998).

Most tomographic models for spatial wavelengths larger than 1000 km, which approximately corresponds to harmonic degree of 40, agree that down to about 250–300 km, the deep upper mantle structure is closely related to plate tectonics and

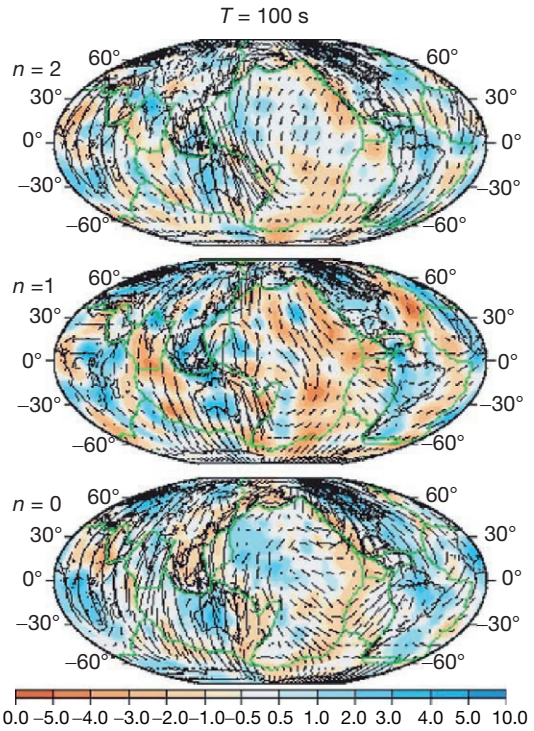

Figure 6 Rayleigh-wave phase velocity maps at period $T=100$ s for the first three modes ($n=0$, 1, 2). Reproduced from Beucler E and Montagner J-P (2006) Computation of large anisotropic seismic heterogeneities. *Geophysical Journal International* 165: 447–468.

continental distribution. **Figure 7** presents two horizontal cross sections from the model of Debayle et al. (2005), which illustrates and confirms the robust features of the upper mantle models published so far since Montagner and Tanimoto (1991). In the upper mantle depth range around 100 km, all plate boundaries are slow: Ridges and back-arc areas are slow, shields are fast, and seismic velocity in oceanic areas is increasing with the age of the seafloor. Except at very few places, it is found that radial anisotropy expressed through the ξ parameter ($\xi=(V_{SH}^2-V_{SV}^2)/V_{SV}^2$) is positive, as large as 10% in some oceanic areas and decreases with depth.

The amplitude of SV-wave azimuthal anisotropy (G parameter) presents an average value of about 2% below oceanic areas (**Figure 7(b)**). Montagner (1994, 2002) noted a good correlation between seismic azimuthal anisotropy and plate velocity directions (primarily for fast-moving plates) given by Minster and Jordan (1978) or DeMets et al. (1991). However, the azimuth of G parameter can vary significantly as a function of depth. For instance, at shallow depths (down to 60 km), the maximum velocity can be parallel to mountain belts or plate boundaries (Babuska et al., 1998; Silver, 1996; Vinnik et al., 1992), but orthogonal to them at large depth. This means that, at a given place, the orientation of fast axis is a function of depth, which explains why the interpretation of SKS splitting with a simple model is often difficult (Becker et al., 2003; Montagner et al., 2000). But Marone and Romanowicz (2007a,b) showed that the introduction of anisotropy stratification in the North American upper mantle makes it possible to resolve the discrepancy between surface wave-derived and

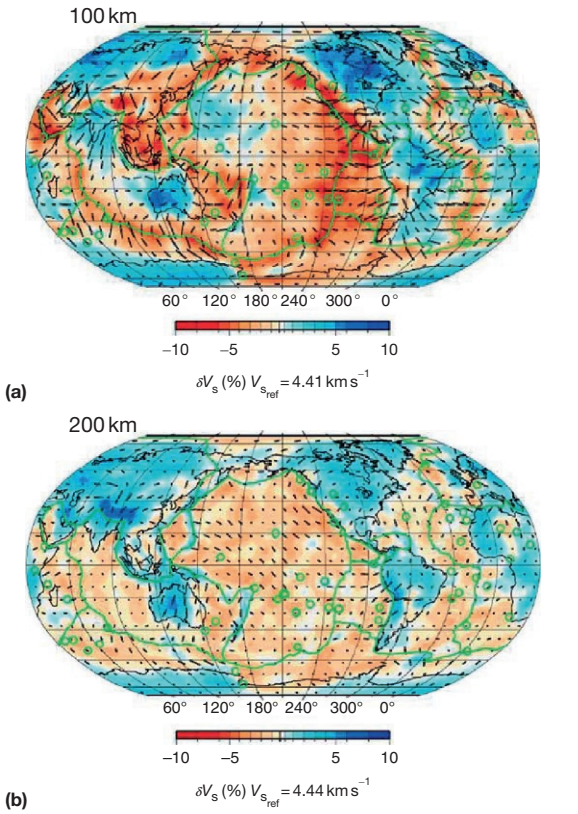

Figure 7 (a, b) Two cross sections at 100 km (top) and 200 km (bottom) depths of the global tomographic model of Debayle et al. (2005). Directions of azimuthal anisotropy are superimposed on S-wave velocity heterogeneities. The length of bars is proportional to its amplitude (<2%).

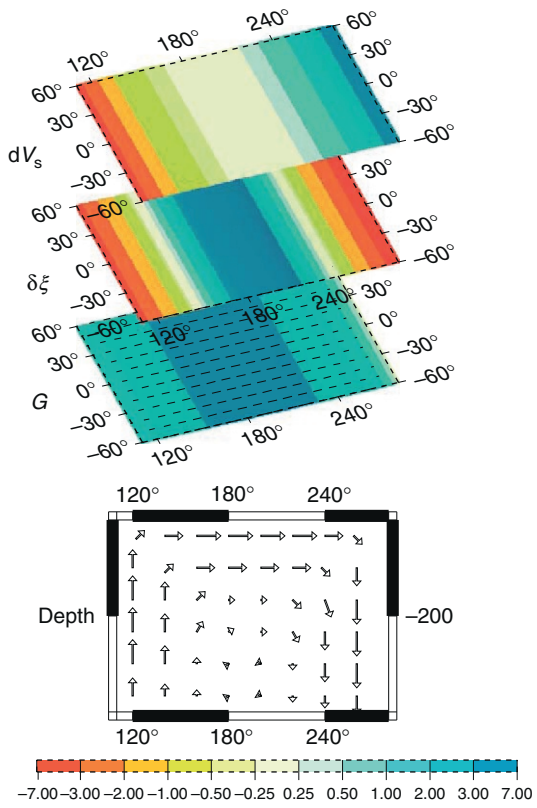

Figure 8 Horizontal cross sections of the seismic observable parameters V_S, ξ, G, Ψ_G associated with a simple convecting cell in the upper mantle, assuming lattice-preferred orientation of anisotropic minerals such as olivine. A vertical flow is characterized by a negative ξ radial anisotropy (ratio between V_{SH} and V_{SV}) and a small azimuthal anisotropy ($G \approx 0$). An upwelling (resp. downwelling) is characterized by a large positive (resp. negative) temperature anomaly inducing $\delta V_S < 0$ (resp. $\delta V_S > 0$). A predominant large-scale horizontal flow will be translated into a significant amplitude of the G azimuthal anisotropy and its orientation will reflect the direction of flow (with a 180° ambiguity). Reproduced from Montagner J-P (2002) Upper mantle low anisotropy channels below the Pacific plate. *Earth Planetary Science Letters* 202: 205–227.

surface wave-observed shear-wave splitting, which was confirmed by Yuan and Romanowicz (2010).

As depth increases, the amplitude of heterogeneities rapidly decreases, some trends tend to vanish, and some distinctive features come up: Most fast ridges are still slow but slow ridges are hardly visible and back-arc regions are no longer systematically slow below 200 km. Large portions of fast ridges are offset with respect to their surface signatures. Below 300 km of depth (not shown here), high-velocity body below the western and the eastern Pacific Rim is the most striking feature, which can be related to subducting slabs.

A visual and quantitative comparison of existing models can be found at the following website addresses: http://igppweb.ucsd.edu/~gabi/rem.html (Reference Earth Model (REM) project) and http://geodynamics.usc.edu/~becker/tdata.html.

1.19.4 Geodynamic Applications

The most popular application of large-scale tomographic models is the understanding of mantle convection. Seismic velocity anomalies can be converted, under some assumptions, not only into temperature anomalies and density anomalies but also into chemical or mineralogical heterogeneities. The application of seismic anisotropy to geodynamics in the upper mantle is straightforward, if we assume that seismic anisotropy is primarily due to the lattice-preferred orientation (LPO) of anisotropic crystals such as olivine (Christensen and Lundquist, 1982; Mainprice et al., 2000; Nicolas et al., 1973). The fast-polarization axis of mineralogical assemblages is in the flow plane parallel to the direction of flow. **Figure 8** shows what is expected for the observable parameters V_S, ξ, G, ψ_G in the case of a simple convective cell with LPO. Radial anisotropy ξ expresses the vertical ($\xi < 1$) or horizontal character ($\xi > 1$) of convective flow, and the azimuthal anisotropy **G** can be related to the horizontal flow direction. Conversely, the three maps of V_S, ξ, **G** can be interpreted in terms of convective flow. These three pieces of information are necessary to correctly interpret the data. For example, upwellings and downwellings are both characterized by a weak or negative ξ parameter, but a correlative positive or negative δV_S discriminates between these possibilities. By simultaneously inverting at depth for the different

azimuthal terms of Rayleigh and Love waves, it is therefore possible to separate the lateral variations in temperature from those induced by the orientation of minerals.

Such an interpretation might however be erroneous in water-rich mantle regions where LPO of minerals such as olivine is not simply related to the strain field (e.g., Jung and Karato, 2001). In addition, the causes of seismic anisotropy are not unique. Other processes can give rise to apparent anisotropy. A purely isotropic finely layered medium with an average layer thickness much less than seismic wavelength will give rise to radial anisotropy (Backus, 1962). Cracks and fluid inclusions (due, e.g., to partial melting) embedded in rocks aligned parallel to the main compressive stress field through the mechanism of shape-preferred orientation (SPO) can also produce a significant anisotropy when its scale is much less than the seismic wavelength. The discrimination between intrinsic anisotropy (related to LPO mechanism) and extrinsic anisotropy (related to SPO or fine layering) is a difficult problem and must be carefully addressed in order to avoid wrong interpretations of apparent anisotropy.

We will only present some examples of interesting applications of anisotropy in large-scale geodynamics and tectonics. Seismic anisotropy in the mantle primarily reflects the strain field prevailing in the past (frozen-in anisotropy) for shallow layers or present convective processes in deeper layers. Therefore, it makes it possible to map convection in the mantle. It must be noted that, when only the radial anisotropy is retrieved, its interpretation is nonunique. A fine layering of the mantle (Backus, 1962) or partial melting (Kawakatsu et al., 2009) can also generate such a kind of anisotropy, and neglecting the azimuthal anisotropy can bias the amplitude of radial anisotropy and its interpretation.

The uppermost mantle down to 410 km is the depth range where the existence of seismic anisotropy is now widely recognized and well documented. Azimuthal variations have been found for body waves and surface waves in different areas of the world. During the last years, the shear-wave splitting, primarily for SKS waves, was extensively used to study continental deformation, but very few studies using body waves are devoted to oceanic areas (except in oceanic islands). Conversely, global anisotropic upper mantle models have been primarily derived during the last 20 years from surface waves, which are sensitive to structure below oceanic areas in the absence of ocean bottom stations and consequently of dense body wave data. The intercomparison of anisotropic body wave and surface wave data is presently ongoing. As shown by Montagner et al. (2000), Wüstefeld et al. (2009), and Becker et al. (2012) at the global scale, such a comparison is providing encouraging results.

1.19.4.1 Oceanic Plates

Oceans are the areas where plate tectonics applies almost perfectly and this is particularly the case in the largest one, the Pacific Plate. **Figure 9** presents examples of three vertical cross sections at two different latitudes, displaying V_{SV} velocity anomalies (**Figure 9(a)**) and the two kinds of anisotropy, which can be retrieved by simultaneous inversion of Rayleigh-wave and Love-wave constant 0-Ψ and azimuthal terms of eqn [1] from the model of Montagner (2002). In **Figure 9(b)**, the equivalent radial anisotropy of the medium, for S-wave expressed through the ξ parameter, is displayed. The maps of **Figure 9(c)** are the distributions of the G parameter related to the azimuthal variation of SV-wave velocity. The maximum amplitude of G is around 5% and rapidly decreases as depth increases. The distribution of velocity and anisotropy is completely different for these different cross sections. The thickening of lithosphere with the age of the seafloor is well observed on V_{SV} velocity maps, but lithosphere is much thicker in the northern cross section. When compared with the cooling half-space model, bathymetry, heat flux, and lithospheric thickness flatten with age (see Maggi et al., 2006; Ritzwoller et al., 2004, for recent results). This flattening is explained by basal reheating, especially in the central Pacific and the birth of small-scale convection below the lithosphere (Davaille and Jaupart, 1994; Huang et al., 2003; Richter and Parsons, 1975; Solomatov and Moresi, 2000).

Radial cross sections (**Figure 9(b)**) show that the $\delta\xi = \xi - \xi_{PREM}$ parameter is usually negative and small, where flow is primarily radial (mid-ocean ridges and subduction zones). For the East Pacific Rise (EPR), Gu et al. (2005) found that a negative radial anisotropy is observed at least down to 300 km. Between plate boundaries, oceans display very large areas with a large positive radial anisotropy such as in the Pacific Ocean (Ekström and Dziewonski, 1998), characteristic of an overall horizontal flow field. This very large anisotropy in the asthenosphere might be the indication of a strong deformation field at the base of the lithosphere (Gung et al., 2003), corresponding to the upper boundary layer of the convecting mantle (Anderson and Regan, 1983; Montagner, 1998). The nature of the boundary between lithosphere and asthenosphere (usually named LAB) has been questioned, and the large shear-wave velocity reduction with the rapid increase in radial anisotropy at the LAB requires a partially molten asthenosphere consisting of horizontal melt-rich layers embedded in meltless mantle (Kawakatsu et al., 2009).

Since convective flow below oceans is dominated by large-scale plate motions, the long-wavelength anisotropy found in oceanic lithospheric plates and in the underlying asthenosphere should be similar to the high-resolution anisotropy measured from body waves. Incidentally, one of the first evidences of azimuthal anisotropy was found in the Pacific Ocean by Hess (1964) for Pn-waves. So far, there are very few measurements of anisotropy by SKS splitting in the oceans. When seismic stations on the seafloor (with the exception of H_2O halfway between Hawaii and California) are lacking, the only measurements available for SKS were performed in stations located on ocean islands (Ansel and Nataf, 1989; Barruol and Fontaine, 2013; Fontaine et al., 2007; Kuo and Forsyth, 1992; Russo and Okal, 1999; Wolfe and Silver, 1998), which are by nature anomalous objects, such as volcanic hot spots, where the strain field is perturbed by the upwelling material and not necessarily representative of the main mantle flow field. Walker et al. (2001) presented a first measurement of SKS splitting at H_2O, but it is in disagreement with independent SKS splitting measurements at the same station by Vinnik et al. (2003) and with surface wave anisotropy (Montagner, 2002). Recently, several ocean seismic experiments have been carried out at regional scale, mainly in the Pacific Ocean. SKS splitting was measured during the temporary MELT experiment (Forsyth et al., 1998;

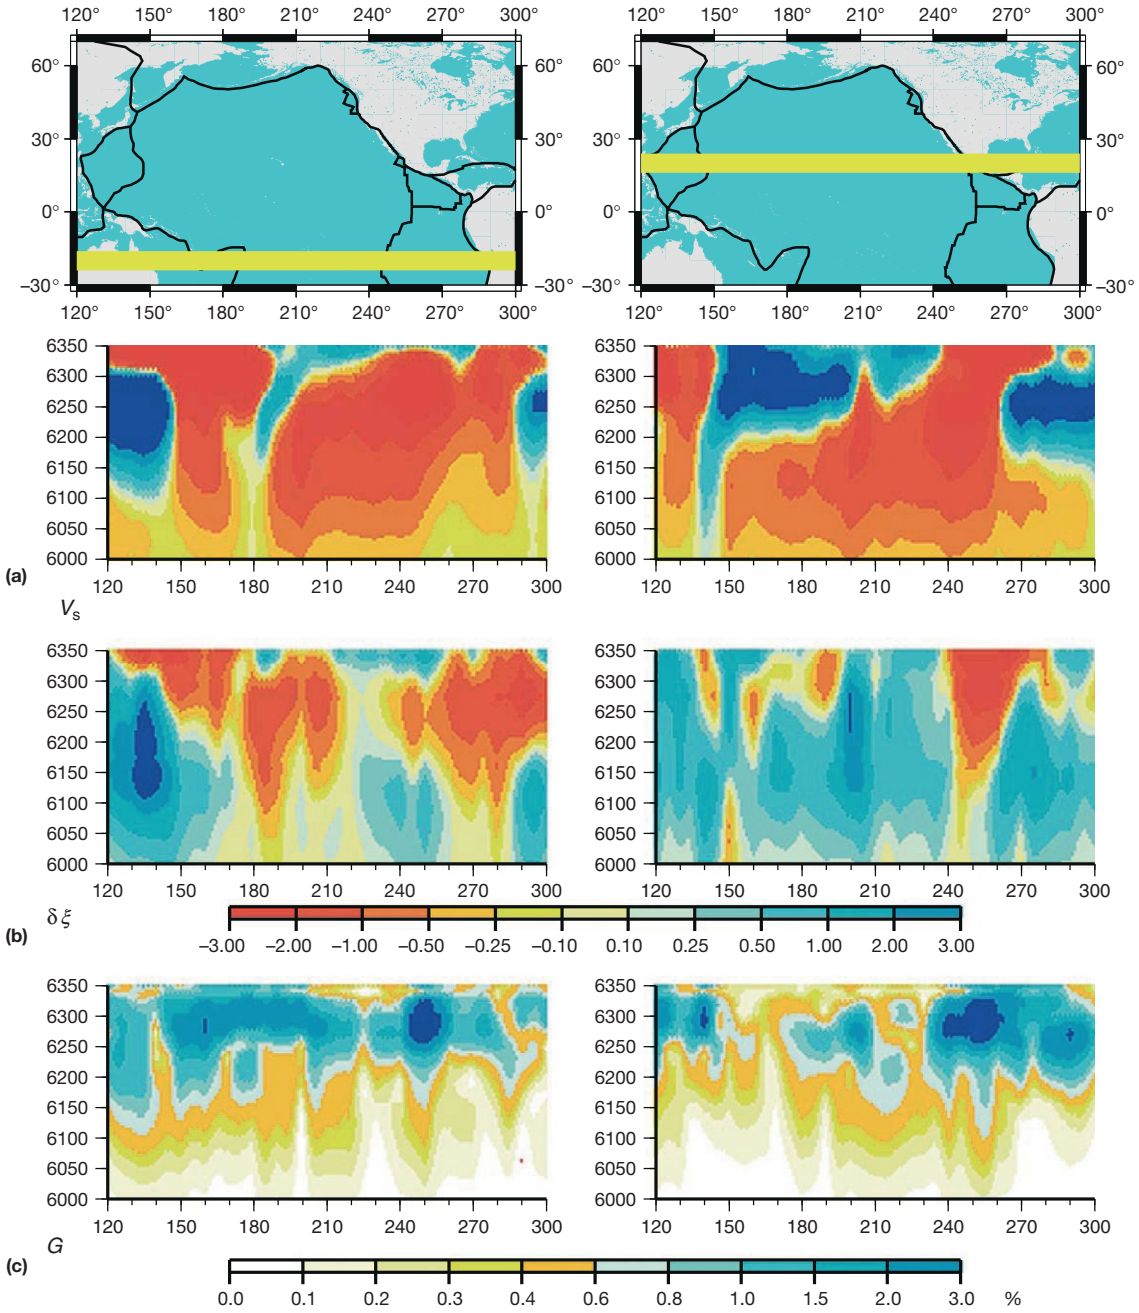

Figure 9 Vertical cross sections of the distribution of V_S, $\xi - \xi_{\rho\varepsilon\phi}$, G in the Pacific Plate at −20° south and 20° north between radii 6000 km (370 km depth) and 6350 km (20 km depth).Reproduced from Montagner J-P (2002) Upper mantle low anisotropy channels below the Pacific plate. *Earth and Planetary Science Letters* 202: 205–227. The color scales in percents are the same for V_S and ξ. The vertical scale is exaggerated to make the figures more readable. Wolfe and Solomon, 1998) and GLIMPSE experiment (Harmon et al., 2004) on the EPR, but the orientation of the splitting is in disagreement with the petrologic predictions of Blackman et al. (1996).

The large-scale azimuthal anisotropy within and below the lithosphere in the depth range 100–300 km is closely related to plate motions (Becker et al., 2012; Ekström, 2000; Maggi et al., 2006; Montagner, 1994) and modeled in this framework (Tommasi et al., 1996). Fast moving oceanic plates are zones where the comparison between directions of plate velocities (Minster and Jordan, 1978) or NUVEL-1 (DeMets et al., 1991) and directions of G parameter is the most successful (**Figure 10**). Conversely, such a comparison is more difficult and controversial below plates bearing a large proportion of continents, such as the European–Asian plate, characterized by a very small absolute motion in the hot spot reference frame and probably a large influence of inherited anisotropy.

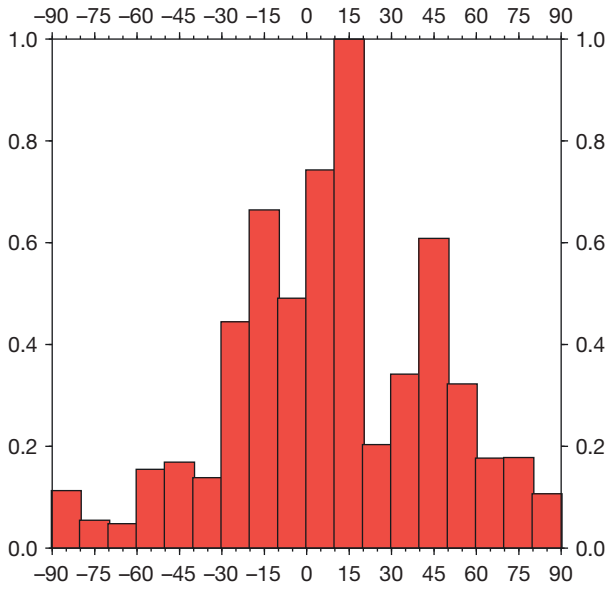

Figure 10 Histogram of the difference between plate velocity directions and synthetic SKS anisotropic azimuths in the Pacific Plate. It is calculated by summing the contributions of each grid point (5° × 5°) weighted by the latitude and the amplitude of anisotropy. Modified from Montagner J-P (2002) Upper mantle low anisotropy channels below the Pacific plate. *Earth and Planetary Science Letters* 202: 205–227.

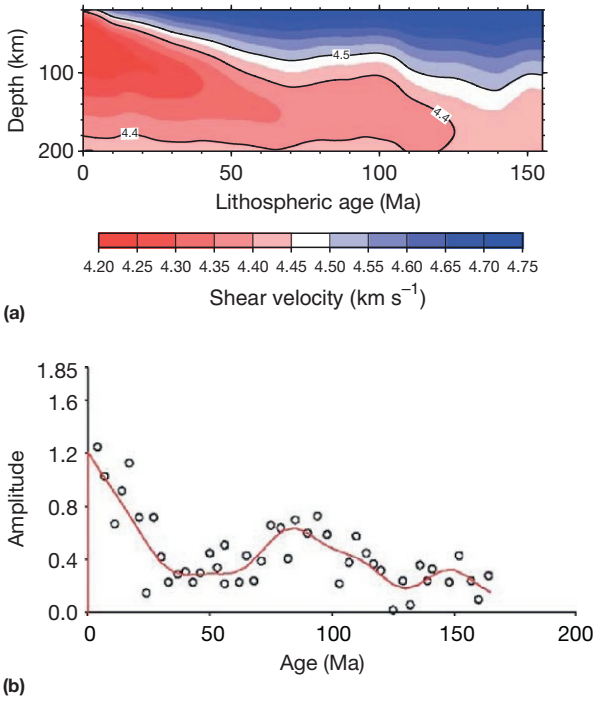

Figure 11 Variations of (a) average S-wave velocity and (b) azimuthal anisotropy (through the delay time of synthetic SKS splitting) plotted versus the age of lithospheric seafloor. In both cases, the structure below the plate for age between 60 and 100 Ma looks anomalous. (a) Modified from Ritzwoller MH, Shapiro NM, and Zhong S-J (2004) Cooling history of the Pacific lithosphere. *Earth and Planetary Science Letters* 226: 69–84. (b) Reproduced from Montagner J-P (2002) Upper mantle low anisotropy channels below the Pacific plate. *Earth and Planetary Science Letters* 202: 205–227.

The map with the *G* parameter at 100 km (**Figure 7**) and the cross sections of **Figure 9(c)** show that the azimuthal anisotropy is very large along spreading ridges with a large asymmetry for the EPR. The direction of anisotropy is in very good agreement with plate motion, which is also found in all other available models (Debayle et al., 2005; Ekström, 2000; Lebedev and van der Hilst, 2008; Smith et al., 2004). The anisotropy is also large in the middle of the Pacific Plate, but a line of very small azimuthal anisotropy almost parallel to the EPR is observed there (see also **Figure 4** for synthetic SKS). This linear area of small anisotropy was named low anisotropy channel (LAC) by Montagner (2002). When calculating the variation of the amplitude of azimuthal anisotropy as a function of depth, a minimum comes up between 40 and 60 Ma age of the seafloor (**Figure 11(a)**). The LAC is presumably related either to cracking within the Pacific Plate or to secondary convection within and below the rigid lithosphere, predicted by numerical and analog experiments and also translated in the V_S velocity structure (Ritzwoller et al., 2004; **Figure 11(b)**). These new features provide strong constraints on the decoupling between the plate and asthenosphere. The existence and location of these LACs might be related to the current active volcanoes and hot spots (possibly plumes) in the central Pacific. LACs, which are dividing the Pacific Plate into smaller units, might indicate a future reorganization of plates with ridge migrations in the Pacific Ocean. They call for more thorough numerical modeling.

1.19.4.2 Continents

Differences in the thickness of high-velocity layer underlying continents as imaged by seismic tomography have fuelled a long debate on the origin of continental roots and its depth suggested down to 400 km (Jordan, 1975, 1978). Most global tomographic models provide a continental thickness of about 200–250 km in agreement with heat-flow analysis or electric conductivity.

Seismic anisotropy can provide fundamental information on the structure of continents, their root, and the geodynamic processes involved in mountain building and collision between continents (Silver, 1996; Vinnik et al., 1992) such as in Central Asia (Griot et al., 1998a,b; Priestley et al., 2006; Yao et al., 2010). Radial anisotropy ξ is usually very heterogeneous below continents in the first 150–200 km of depth with positive or negative areas according to geology. But it seems to display a systematic tendency of being positive at larger depth (down to 300 km), whereas it is very large in the oceanic lithosphere in the depth range 50–200 km and decreases rapidly at larger depths (Montagner, 1994). Conversely, radial anisotropy displays a maximum (though smaller than in oceanic lithosphere) below very old continents (such as Siberian and Canadian Shields) in the depth range 200–400 km (Montagner and Tanimoto, 1991), which might be a good marker of LAB below continents. Seismic anisotropy below continents, sometimes confined to the upper 220 km (Gaherty and Jordan, 1995), can still be significant below. A more quantitative comparison of radial anisotropy between different continental provinces is presented in Babuska et al. (1998) and

demonstrates systematic differences according to the tectonic context. The existence of positive large-scale radial anisotropy below continents at depth might be a good indicator of the continental root, which was largely debated since the presentation of the model of tectosphere by Jordan (1975, 1978, 1981). If this maximum of anisotropy is assumed to be related to an intense strain field in this depth range, it might be characteristic of the boundary between continental lithosphere and 'normal' upper mantle material. Gung et al. (2003) showed that it is possible to reconcile different isotropic tomographic models by taking into account radial anisotropy. They find that significant radial anisotropy (with $V_{SH} > V_{SV}$) under most cratons in the depth range 250–400 km is similar to that found at shallower depths (80–250 km) below oceanic basins. Such a result is also in agreement for the Australian continent (Debayle and Kennett, 2000; Simons et al., 2002). So, all results seem to show that the root of continents as defined by radial anisotropy is located between 200 and 300 km. However, this result is not correlated with a maximum in azimuthal anisotropy in this depth range (Debayle et al., 2005): the fast-moving Australian Plate seems to be the only continental region with a sufficiently large deformation at its base to be transformed into azimuthal anisotropy. They propose that, for continents other than Australia, weak influence of basal drag on the lithosphere may explain why azimuthal anisotropy is observed only in a layer located in the uppermost 100 km of the mantle. This layer shows a complex organization of azimuthal anisotropy, suggesting a frozen-in origin of deformation, compatible with SKS splitting. This complexity is probably related to the stratification of anisotropy within cratons (Deschamps et al., 2008). The issue of the depth of continental roots is still a subject of debate. With the rapid expansion of permanent or temporary broadband seismic stations in different continents, it has been possible to carry out extensive investigations of LAB using receiver functions. Whereas global and regional surface wave anomalies in the mantle beneath old continents like Africa, Australia, and North America (e.g., Marone and Romanowicz, 2007a; Montagner and Tanimoto, 1991; Nettles and Dziewonski, 2008; Woodhouse and Dziewonski, 1984) have found continental roots down to 200–250 km depths, receiver functions studies (Kumar et al., 2007) found that the Indian lithosphere is significantly thinner (~100 km thick). The global investigation of the LAB by Rychert and Shearer (2009) imaged an interface varying from 100 km beneath Precambrian shields to 80 km beneath tectonically altered regions. In order to reconcile the contradictory results, Yuan and Romanowicz (2010) proposed a lithospheric layering of the North American craton. By mapping the changes in the direction of azimuthal anisotropy, they reveal the presence of two distinct lithospheric layers throughout the stable part of the North American continent. Taking a comparative note of these studies, the receiver function results could indicate an inner layering of continental lithosphere. This kind of investigation must be performed on all continents in order to generalize this finding (e.g., Romanowicz, 2009).

The difference in radial and azimuthal anisotropies between oceans and continents might reflect a difference of coupling between lithosphere and asthenosphere, through the basal drag. The coupling might be weak below most continental roots, in contrast with the Pacific Plate, where the coupling (reflected by plate direction) is the first-order effect in the uppermost 200 km for young ages, before thermal instabilities take place at the base of the lithosphere, as evidenced by the existence of LACs. These results on the difference between oceanic and continental anisotropies are illustrated in Figure 12.

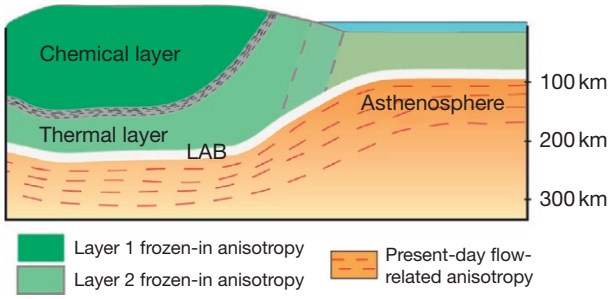

Figure 12 Scheme illustrating the inferred stratification of the lithosphere as derived from seismic anisotropy. It also illustrates the difference in the location of maximum anisotropy between oceans and continents. Adapted from Yuan HY and Romanowicz B (2010) Lithospheric layering in the North American craton. *Nature* 466: 1063–1068. http://dx.doi.org/10.1038/nature09332.

1.19.4.3 Velocity and Anisotropy in the Transition Zone

The transition zone (see also **Chapter 1.21**) plays a key role in mantle dynamics, particularly the 660 km discontinuity that might inhibit the passage of matter between the upper lower mantle and the lower mantle and might be a water reservoir (Bercovici and Karato, 2003). Its seismic investigation is made difficult on the global scale by the poor sensitivity of fundamental surface waves in this depth range and by the fact that teleseismic body waves recorded at continental stations from earthquakes primarily occurring along plate boundaries have their turning point below the transition zone. For body waves, many different techniques using SS precursors (Shearer, 1991) or P-to-S converted waves (Chevrot et al., 1999) were used at global scale to investigate the thickness of the transition zone. In spite of some initial controversies, more recent models by Lawrence and Shearer (2006), Houser et al. (2008), and Tauzin et al. (2008) provide a coherent large-scale image of the transition zone thickness.

Whatever the type of data (normal mode, higher modes of surface waves, and body waves), an important feature of the transition zone is that, contrary to the rest of the upper mantle, the upper transition zone is characterized by a large degree-2 pattern (Masters et al., 1982) and, to a lesser extent, a strong degree-6. The degree-2 pattern (as well as degree-6) can be explained by the predominance of a simple large-scale flow pattern characterized by two upwellings in the central Pacific Ocean and East Africa and two downwellings in the western and eastern Pacific Ocean (Montagner and Romanowicz, 1993), proposed initially in the lower mantle (Busse, 1983). This scheme was corroborated by the existence, in the upper transition zone, of a slight but significant degree-4 radial anisotropy displayed by Montagner and Tanimoto (1991) and Roult et al. (1990) in agreement with the prediction of this model. Therefore, the observations of the geographic distributions of degrees 2, 4, and 6 in the transition zone are

coherent and spatially dependent. Montagner (1994) compared these different degrees to the corresponding degrees of the hot spot and slab distribution. In this simple framework, the distribution of plumes (degree $2+6$) is merely a consequence of the large-scale simple flow in the transition zone. The degree 6 of velocity in the transition zone is well correlated with the distribution of hot spots and might indicate that many mantle plumes might originate in the transition zone. Ritsema et al. (2004) observed lower-than-average shear velocity at eight hot spots in this depth range (**Figure 13**). These results suggest that there are different families of plumes, some of them originating in the transition zone.

As for anisotropy in the transition zone, Montagner and Kennett (1996), by using eigenfrequency data, displayed some evidence of radial anisotropy in the upper (410–660 km) and lower (660–900 km) transition zones. Panning and Romanowicz (2004) also displayed a slight maximum of the harmonic degree 0 in the transition zone. Global tomographic models (Kustowski et al., 2008a,b; Panning and Romanowicz, 2006) display significant lateral variations of radial anisotropy in the transition zone, in particular below subduction zones. The existence of anisotropy close to the 660 km discontinuity was also found by Vinnik and Montagner (1996) below Germany and Vinnik et al. (1998) in Central Africa. By studying P-to-S converted waves at the GRF network and at GEOSCOPE station BNG in Central Africa, they observed that part of the initial P-wave is converted into SH-wave. This signal can be observed on the transverse component of seismograms. The amplitude of this SH-wave cannot be explained by a dipping 660 km discontinuity and it constitutes a good evidence for the existence of anisotropy just above this discontinuity. However, there is some evidence of lateral variation of anisotropy in the transition zone as found by the investigation of several subduction zones (Fischer and Wiens, 1996; Fischer and Yang, 1994). Fouch and Fischer (1996) presented a synthesis of these different studies and showed that some subduction zones such as Sakhalin require deep anisotropy in the transition zone, whereas others such as Tonga do not need any anisotropy. They conclude that their data might be reconciled by considering the upper transition zone (410–520 km) intermittently anisotropic, and the rest of the transition zone might be isotropic.

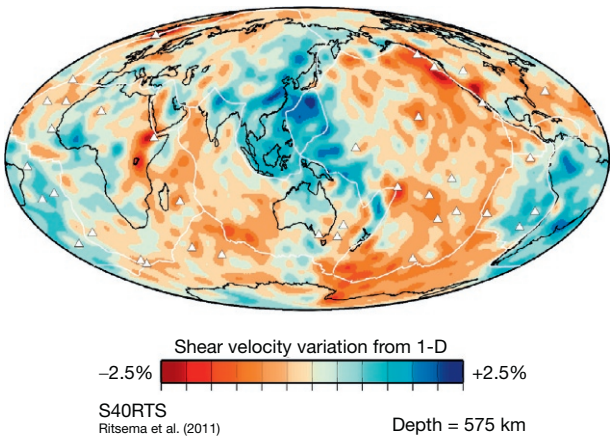

Figure 13 Model of shear velocity in the transition zone at 575 km depth derived from the inversion of fundamental-mode and overtone Rayleigh-wave phase velocities and teleseismic body wave data. Modified from Ritsema J, Deuss A, van Heijst HJ, and Woodhouse JH (2011) S40RTS: A degree-40 shear-velocity model for the mantle from new Rayleigh wave dispersion, teleseismic traveltime and normal-mode splitting function measurements. *Geophysical Journal International* 184: 1223–1236.

Azimuthal anisotropy in the transition zone was also advocated by two independent studies, using different datasets. The observations of Wookey et al. (2002), though controversial, present evidence of very large S-wave splitting (up to 7 s) in the vicinity of the 660 km discontinuity between Tonga–Kermadec Subduction Zone and Australia. On a global scale, Trampert and van Heijst (2002) showed a long-wavelength azimuthal anisotropic structure in the transition zone. The rms amplitude of lateral variations of G is about 1%. Beghein and Trampert (2003) using probability density functions and separating ξ, ϕ, and η anisotropies suggested a chemical component to explain these different parameters. The interpretation of these new tentative results is not obvious and new data are necessary to close the debate on the nature of velocity and anisotropy heterogeneities in the transition zone. The transition zone might be a midmantle boundary layer, and a detailed and reliable tomographic model of S-wave velocity and anisotropy in the transition zone will provide fundamental insights into the dynamics of the whole mantle.

1.19.5 Numerical Modeling and Perspectives

In the previous sections, we have highlighted the presence of lateral heterogeneities in seismic velocity and anisotropy in different parts of the Earth's upper mantle. However, anisotropy is not present in all depth ranges nor at all scales. There is some consensus for the presence of radial anisotropy in many parts of the upper mantle in order to simultaneously explain Love-wave and Rayleigh-wave dispersions and even in the lower mantle (Kustowski et al., 2008a,b; Panning and Romanowicz, 2004). The existence of azimuthal anisotropy is more controversial, though, from petrologic reasons, it turns out that radial anisotropy and azimuthal anisotropy are intimately related and should be searched for simultaneously. Additional data such as polarization data might help to provide additional constraints on both kinds of anisotropy (Pettersen and Maupin, 2002; Yu and Park, 1993). But it requires the development of improved theoretical and numerical methods in order to work on the amplitude of seismograms.

Thanks to the access to very powerful computers, we are at the beginning stage of a new era for seismology. The twentieth century was dominated by the use of ray theory and, later on, of normal mode theory. Since it is now feasible to numerically compute synthetic seismograms in complex 3-D structures in global spherical geometry (Capdeville et al., 2003; Komatitsch and Tromp, 1999; Komatitsch and Vilotte, 1998), it is possible to model the complex interaction between seismic waves and 3-D heterogeneity, particularly in anisotropic and anelastic media. Some new and sophisticated tomographic methods are presently developed (Capdeville et al., 2005; Fichtner et al., 2009; Lekic and Romanowicz 2011; Montelli et al., 2004; Sigloch et al., 2008; Tromp et al., 2005; Zhou et al., 2006; Zhu et al., 2012) that takes account of finite-frequency

effect and inverted full seismic waveforms. They should provide access to the complexity of the Earth's mantle by the mapping of short-scale heterogeneities such as mantle plumes and slabs in anisotropic and anelastic media.

A second important challenge is the complete understanding of the origin of anisotropy from the mineral scale up to global scale in the different layers of the Earth. In the upper mantle, seismic anisotropy is primarily due to LPO of anisotropic minerals such as olivine at large scales, requiring several strong conditions, starting with the presence of anisotropic crystals up to the existence of an efficient large-scale present or past strain field (Mainprice et al., 2000). In order to fill the gap between grain-scale modeling (Kaminski and Ribe, 2001; McKenzie, 1979; Ribe, 1989) and large-scale anisotropic measurements in a convective system (Tommasi et al., 2000), there is now a real need to make more quantitative comparisons between seismic anisotropy and numerical modeling. Gaboret et al. (2003), Becker et al. (2003), and Conrad et al. (2007) calculated the convective circulation in the mantle by converting perturbations of S-wave velocity into density perturbations. **Figure 14** shows two cross sections through the Pacific hemisphere and the associated flow lines (Gaboret et al., 2003) derived from the tomographic model of Ekström and Dziewonski (1998). This kind of modeling makes it possible to calculate the strain tensor and to test different hypotheses for the prevailing mechanisms of alignment, by comparison with seismic data. The joint interpretation of seismic and geodynamic data provides fundamental constraints on convective pattern within the mantle and the relative importance of thermal versus compositional heterogeneity (Long and Becker, 2010; Simmons et al., 2009).

The upper mantle is the best known of the deep layers of the earth, where there is now good agreement between many isotropic global tomographic models. But the account of seismic anisotropy is mandatory to avoid biased isotropic heterogeneities. The main application of anisotropy is the mapping of mantle convection and of its boundary layers (Karato, 1998; Montagner, 1998). The finding of anisotropy in the transition zone (if confirmed) will provide strong constraints on the flow circulation and the exchange of matter between the upper and the lower mantle. Pursuing the first pioneering efforts, the systematic modeling of the complete seismic waveform in 3-D heterogeneous, anisotropic, and anelastic media associated with new techniques of numerical modeling of seismograms will probably enhance our vision of the whole mantle.

In parallel to these theoretical and numerical challenges, there is a crucial need for instrumental developments since there are still many areas on the surface of the Earth devoid of broadband seismic stations. These regions are primarily located in the southern hemisphere and more particularly in oceanic areas where no islands are present. Therefore, an international effort is ongoing, coordinated through ION (International Ocean Networks), in order to promote the installation of geophysical ocean bottom observatories in order to fill the enormous gaps in the station coverage (for a description of ION, see http://seismo.berkeley.edu/seismo/ion and http://msg.whoi.edu/ION/index.html).

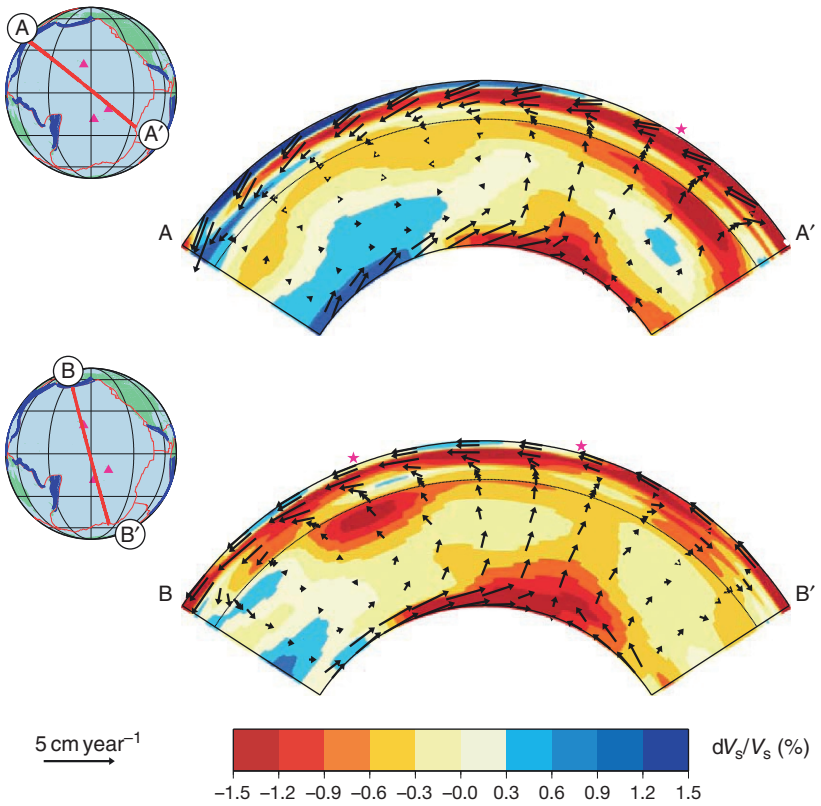

Figure 14 Mantle heterogeneities and convective flow below the Pacific Ocean. Adapted from Gaboret C, Forte A, and Montagner J-P (2003) The unique dynamics of the Pacific Hemisphere mantle and its signature on seismic anisotropy. *Earth and Planetary Science Letters* 208: 219–223.

Appendix Effect of Anisotropy on Surface Waves in the Plane-Layered Medium

See Figure 15.

The half-space is assumed to be homogeneous and may be described by its density $\rho(z)$ and its fourth-order elastic tensor $\Gamma(z)$ with 21 independent elastic coefficients. All these parameters are so far supposed independent of x- and y-coordinates (z is the vertical component). This condition will be released in the next section. The unperturbed medium is assumed isotropic with an elastic tensor $\Gamma_0(z)$. In that medium, the two cases of Love-wave and Rayleigh-wave dispersions can be successively considered.

The unperturbed Love-wave displacement is of the form

$$\mathbf{u}(\mathbf{r},t)=\begin{pmatrix}-W(z)\sin\Psi\\ W(z)\cos\Psi\\ 0\end{pmatrix}\exp(i[k(x\cos\Psi+y\sin\Psi)-\omega t]) \quad [19]$$

where $W(z)$ is the scalar depth eigenfunction for Love waves, k is the horizontal wave number, and Ψ is the azimuth of the wave number k measured clockwise from the north.

The unperturbed Rayleigh-wave displacement is of the form

$$\mathbf{u}(\mathbf{r},t)=\begin{pmatrix}V(z)\cos\Psi\\ V(z)\sin\Psi\\ iU(z)\end{pmatrix}\exp(i[k(x\cos\Psi+y\sin\Psi)-\omega t]) \quad [20]$$

where $V(z)$ and $U(z)$ are the scalar depth eigenfunctions for Rayleigh waves. The associated strain tensor $\epsilon(\mathbf{r},t)$ is defined by

$$\epsilon_{ij}(\mathbf{r},t)=1/2\left(u_{i,j}+u_{j,i}\right) \quad [21]$$

where j denotes the differentiation with respect to the j-th coordinate. The medium is perturbed from $\Gamma_0(z)$ to $\Gamma_0(z)+\gamma(z)$, where $\gamma(z)$ is small compared to $\Gamma_0(z)$ but quite general in the sense that there is no assumption on the kind of anisotropy. This means that in this approximation, we can still consider quasi-Love modes and quasi-Rayleigh modes (Crampin, 1984). From Rayleigh's principle, the first-order perturbation $\delta V(\mathbf{k})$ in phase velocity dispersion is (Smith and Dahlen, 1973, 1975)

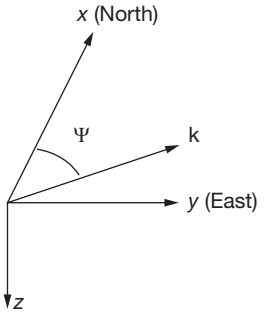

Figure 15 Definition of the Cartesian coordinate system (x, y, z) used in the calculations. Ψ is the azimuth of the wavevector k with respect to north.

$$\delta V(\mathbf{k})=\frac{V}{2\omega^2}\frac{\int_0^\infty \gamma_{ijkl}\epsilon_{ij}\epsilon_{kl}^*}{\int_0^\infty \rho_0 u_k u_k^*}\mathrm{d}z \quad [22]$$

where u and ϵ_{ij} are, respectively, the displacement and the strain for the unperturbed half-space and the asterisk denotes complex conjugation. Now because of the symmetry of the tensors $\gamma(z)$ and ϵ, we use the simplified index notation c_{ij} and ϵ_i for the elements γ_{ijkl} and ϵ_{ij}, but the number n_{ij} of coefficients γ_{ijkl} for each c_{ij} must be taken into account. The simplified index notation for the elastic tensor γ_{ijkl} is defined in a coordinate system (x_1, x_2, x_3) by

$$\gamma_{ijkl}\rightarrow c_{pq}\begin{cases}\text{if } i=j\Rightarrow p=i\\ \text{if } k=l\Rightarrow q=k\\ \text{if } i\neq j\Rightarrow p=9-i-j\\ \text{if } k\neq l\Rightarrow q=9-k-l\end{cases} \quad [23]$$

This kind of transformation enables us to relate the fourth-order tensor γ ($3\times3\times3\times3$) to a matrix c (6×6). The same simplified index notation can be applied to the components of the strain tensor ϵ_{ij}, transforming the second-order tensor ϵ (3×3) into a vector with six components. However, it is necessary to be careful, because to a given c_{pq} correspond several γ_{ijki}, and γ_{ijkl} must be replaced by $n_{pq}c_{pq}$, where n_{pq} is the number of γ_{ijki} giving the same c_{pq}. Therefore, eqn [22] expressing Rayleigh's principle can be rewritten as

$$\delta V(k)=\frac{V}{2\omega^2}\frac{\int_0^\infty \sum_{ij} n_{ij}c_{ij}\epsilon_i\epsilon_j^*}{\int_0^\infty \rho_0 u_k u_k^*}\mathrm{d}z \quad [24]$$

We only detail the calculations for Love waves:

By using the previous expressions for $\mathbf{u}(\mathbf{r},t)$ [19] and $\epsilon_{ij}(\mathbf{r},t)$ [21], the various expressions of strain are as follows:

$$\begin{cases}\epsilon_1=-i\cos\Psi\sin\Psi kW\\ \epsilon_2=i\cos\Psi\sin\Psi kW\\ \epsilon_3=0\\ \epsilon_4=1/2\cos\Psi W'\\ \epsilon_5=-1/2\cos\Psi W'\\ \epsilon_6=i/2(\cos^2\Psi-\sin^2\Psi)kW\end{cases} \quad [25]$$

where $W'=\mathrm{d}W/\mathrm{d}r$. In Table 1, the different terms $n_{ij}c_{ij}\epsilon_i\epsilon_j^*$ are given. We note that when $c_{ij}\epsilon_i\epsilon_j^*$ is a purely imaginary complex, its contribution to $\delta V(K,\Psi)$ is null. When all the contributions are summed, the different terms $\cos^k\Psi\sin^l\Psi$ are such that $k+l$ is even, which is not surprising in the light of the reciprocity principle. Therefore, each term can be developed as a Fourier series in Ψ with only even terms. Finally, it is found

$$\begin{aligned}\delta V_{\mathrm{L}}(k,\Psi)=\frac{V}{2\omega^2 L_0}\int_0^\infty \mathrm{d}z\Bigg\{&k^2W^2\left[\frac{1}{8}(c_{11}+c_{22}-2c_{12}+4c_{66})\right]\\ &+W'^2\left[\frac{1}{2}(c_{44}+c_{55})\right]\\ &+\cos2\Psi W'^2\left[\frac{1}{2}(c_{44}-c_{55})\right]-\sin2\Psi W'^2c_{45}\\ &-\cos4\Psi k^2W^2\left[\frac{1}{8}(c_{11}+c_{22}-2c_{12}-4c_{66})\right]\\ &+\sin4\Psi k^2W^2\left[\frac{1}{2}(c_{26}-c_{16})\right]\Bigg\}\end{aligned} \quad [26]$$

Table 1 Calculation of the various $c_{ij\epsilon_i\epsilon_j}$ for Love waves, with the simplified index notation

n	ij	$c_{ij\epsilon_i\epsilon_j}$
1	11	$c_{11}\alpha^2\beta^2\cdot k^2W^2$
1	22	$c_{22}\alpha^2\beta^2\cdot k^2W^2$
1	33	0
2	12	$-c_{12}\alpha^2\beta^2\cdot k^2W^2$
2	13	0
2	23	0
2	24	0
4	14	$c_{14}\left(-i\alpha^2\beta\right)\cdot\frac{kWW'}{2}$
4	15	$c_{14}\left(i\alpha^2\beta\right)\cdot\frac{kWW'}{2}$
4	16	$c_{16}(-\alpha\beta)\left(\alpha^2-\beta^2\right)\cdot\frac{k^2W^2}{2}$
4	24	$c_{24}\left(-i\alpha^2\beta\right)\cdot\frac{kWW'}{2}$
4	25	$c_{25}\left(-i\alpha\beta^2\right)\cdot\frac{kWW'}{2}$
4	26	$c_{26}(\alpha\beta)\left(\alpha^2-\beta^2\right)\cdot\frac{k^2W^2}{2}$
4	34	0
4	35	0
4	36	0
4	44	$c_{44}\alpha^2\cdot\frac{W'^2}{4}$
8	45	$c_{45}(-\alpha\beta)\cdot\frac{W'^2}{4}$
8	46	$c_{46}(-i\alpha)\left(\alpha^2-\beta^2\right)\cdot\frac{kWW'}{4}$
4	55	$c_{55}\beta^2\cdot\frac{W'^2}{4}$
8	56	$c_{56}(i\beta)\left(\alpha^2-\beta^2\right)\cdot\frac{kWW'}{4}$
4	66	$c_{66}\left(\alpha^2-\beta^2\right)^2\cdot\frac{k^2W^2}{4}$

In the particular case of a transversely isotropic medium with a vertical symmetry axis (also named radial anisotropic medium), we have $c_{11}=c_{22}=\delta A$, $c_{33}=\delta C$, $c_{12}=\delta(A-2N)$, $c_{13}=c_{23}=\delta F$, $c_{44}=c_{55}=\delta L$, $c_{66}=\delta N$, and $c_{14}=c_{24}=c_{15}=c_{25}=c_{16}=c_{26}=0$. The local azimuthal terms vanish and the previous eqn [26] reduces to

$$\delta V_L(k,\Psi)=\frac{1}{2V_L L_0}\int_0^\infty\left\{W^2\delta N+\frac{W'^2}{k^2}\delta L\right\}dz \qquad [27]$$

Therefore, the same expressions as in Takeuchi and Saito (1972, p. 268) is found in the case of radial anisotropy. The 0-Ψ term of eqn [26] corresponds to the averaging over azimuth Ψ, which provides the equivalent transversely isotropic model with vertical symmetry axis by setting

$$\delta N=\frac{1}{8}(c_{11}+c_{22})-\frac{1}{4}c_{12}+\frac{1}{2}c_{66}$$

$$\delta L=\frac{1}{2}(c_{44}+c_{55})$$

If we call C_{ij} the elastic coefficients of the total elastic tensor, we can set

$$N=\rho V_{SH}^2=\frac{1}{8}(C_{11}+C_{22})-\frac{1}{4}C_{12}+\frac{1}{2}C_{66}$$

$$L=\rho V_{SV}^2=\frac{1}{2}(C_{44}+C_{55})$$

According to eqn [26], the first-order perturbation in Love-wave phase velocity $\delta V_L(k,\Psi)$ can then be expressed as

$$\delta V_L(k,\Psi)=\frac{1}{2V_{0L}(k)}[L_1(k)+L_2(k)\cos 2\Psi+L_3(k)\sin 2\Psi+L_4(k)\cos 4\Psi+L_5(k)\sin 4\Psi. \qquad [28]$$

where

$$L_0(k)=\int_0^\infty\rho W^2dz$$

$$L_1(k)=\frac{1}{L_0}\int_0^\infty\left(W^2\delta N+\frac{W'^2}{k^2}\delta L\right)dz$$

$$L_2(k)=\frac{1}{L_0}\int_0^\infty -G_c\left(\frac{W'^2}{k^2}\right)dz$$

$$L_3(k)=\frac{1}{L_0}\int_0^\infty -G_s\left(\frac{W'^2}{k^2}\right)dz$$

$$L_4(k)=\frac{1}{L_0}\int_0^\infty -E_c\cdot W^2dz$$

$$L_5(k)=\frac{1}{L_0}\int_0^\infty -E_s\cdot W^2dz$$

- Rayleigh waves

The same procedure holds for the local Rayleigh-wave phase velocity perturbation δV_R, starting from the displacement given previously (Montagner and Nataf, 1986):

$$\delta V_R(k,\Psi)=\frac{1}{2V_{0_R}(k)}[R_1(k)+R_2(k)\cos 2\Psi+R_3(k)\sin 2\Psi+R_4(k)\cos 4\Psi+R_5(k)\sin 4\Psi. \qquad [29]$$

where

$$R_0(k)=\int_0^\infty\rho\left(U^2+V^2\right)dz$$

$$R_1(k)=\frac{1}{R_0}\int_0^\infty\left[V^2\cdot\delta A+\frac{U'^2}{k^2}\cdot\delta C+\frac{2U'V}{k}\cdot\delta F+\left(\frac{V'}{k}-U\right)^2\cdot\delta L\right]dz$$

$$R_2(k)=\frac{1}{R_0}\int_0^\infty\left[V^2\cdot B_c+\frac{2U'V}{k}\cdot H_c+\left(\frac{V'}{k}-U\right)^2\cdot G_c\right]dz$$

$$R_3(k)=\frac{1}{R_0}\int_0^\infty\left[V^2\cdot B_s+\frac{2U'V}{k}\cdot H_s+\left(\frac{V'}{k}-U\right)^2\cdot G_s\right]dz$$

$$R_4(k)=\frac{1}{R_0}\int_0^\infty E_c\cdot V^2dz$$

$$R_4(k)=\frac{1}{R_0}\int_0^\infty E_s\cdot V^2dz$$

The 13 depth-dependent parameters A, C, F, L, N, B_c, B_s, H_c, H_s, G_c, G_s, E_c, E_s are linear combinations of the elastic coefficients C_{ij} and are explicitly given as follows:

Constant term (0-Ψ azimuthal term: independent of azimuth):

$$A=\rho V_{PH}^2=\frac{3}{8}(C_{11}+C_{22})+\frac{1}{4}C_{12}+\frac{1}{2}C_{66}$$

$$C=\rho V_{PV}^2=C_{33}$$

$$F=\frac{1}{2}(C_{13}+C_{23})$$

$$L=\rho V_{SV}^2=\frac{1}{2}(C_{44}+C_{55})$$

$$N=\rho V_{SH}^2=\frac{1}{8}(C_{11}+C_{22})-\frac{1}{4}C_{12}+\frac{1}{2}C_{66}$$

2-Ψ azimuthal term:

$$\begin{array}{ll} \cos 2\Psi & \sin 2\Psi \\ B_c = \frac{1}{2}(C_{11} - C_{22}) & B_s = C_{16} + C_{26} \\ G_c = \frac{1}{2}(C_{55} - C_{44}) & G_s = C_{54} \\ H_c = \frac{1}{2}(C_{13} - C_{23}) & H_s = C_{36} \end{array}$$

4-Ψ azimuthal term:

$$\begin{array}{ll} \cos 4\Psi & \sin 4\Psi \\ E_c = \frac{1}{8}(C_{11} + C_{22}) - \frac{1}{4}C_{12} - \frac{1}{2}C_{66} & E_s = \frac{1}{2}(C_{16} - C_{26}) \end{array}$$

where indices 1 and 2 refer to horizontal coordinates (1, north; 2, east) and index 3 refers to vertical coordinate. ρ is the density; V_{PH} and V_{PV} are, respectively, horizontal and vertical propagating P-wave velocities; and V_{SH} and V_{SV} are, respectively, the horizontal and vertical polarized S-wave velocities. We must bear in mind that A, C, L, N anisotropic parameters can be retrieved from measurements of the P- and S-wave velocities propagating perpendicular or parallel to the axis of symmetry.

Acknowledgments

I would like to thank Barbara Romanowicz and an anonymous reviewer for their constructive reviews and my colleagues from IPG of Paris.

1.20.1 Introduction

During subduction, lithospheric plates are removed from Earth's surface by descent into the mantle from deep-sea trenches. The subducted part of the plate is called the slab. The slab is colder, and hence heavier, than the surrounding mantle, so the resultant negative buoyancy force is a major factor in driving plate motions. Subduction zones are deeper and less mobile than seafloor spreading centers, where oceanic plates are born. Slab descent in subduction zones along the Circum-Pacific represents a deep sheet-like downwelling of mantle convection, whereas magma ascent in spreading centers along midoceanic ridges is a shallow phenomenon, not corresponding directly to large-scale mantle upwelling. The seismic structure of the seafloor spreading centers has been discussed extensively by Dunn and Forsyth (2007).

A subducting slab is a downward continuation of the surface oceanic plate, marked seismologically by high P-wave and S-wave velocities and low P-wave and S-wave attenuations and geodynamically by low temperature, high density, and negative buoyancy relative to the surrounding mantle. The most reliable indicator of the subducting slab is the positive anomaly of seismic velocity. **Figure 1** shows the depth profiles of the areal proportion of more than x% higher-than-normal velocities for several global P-wave and S-wave tomographic models, where $x = 0.5,\ 0.6, \ldots,\ 1.5$. The P-wave and S-wave models HMSL were obtained by measuring the travel times of long-period body wave phases by cross-correlation techniques. The S-wave model S362ANI was obtained by combining a large data set of surface-wave phase-velocity anomalies, long-period waveforms, and the body-wave travel times; S40RTS by measuring travel times of body waves, phase velocities of surface waves and splitting functions of normal modes from broadband waveform data; and TX2011 by measuring arrival times of multibounce shear waves, core-reflected shear waves, and SKS and SKKS waves (see Figure 4 of Dziewonski and Romanowicz (2007) for the nomenclature). The P-wave model MIT-P08 is based on reported and self-picked arrival times and waveform-based differential travel times for which the finite frequency effect (Kárason and van der Hilst, 2001) is taken into account; GAP_P4, on applying finite frequency kernels (Dahlen et al., 2000; Mercerat and Nolet, 2013) to all the datasets of reported and self-picked travel times and waveform-based differential travel times, including those from ocean-bottom seismometers; and LLNL-G3Dv3, on applying a global multiple event locator to reprocess the reported arrival times. See Thurber and Ritsema (2007) for the review of seismic tomography.

In **Figure 1**, all the model profiles exhibit extrema in the three depth ranges, the uppermost mantle, the transition zone, and the lowermost mantle, which are diagnostic of lithospheric plates on the surface, stagnant slabs in the transition zone (Fukao et al., 1992; van der Hilst et al., 1991), and slab graveyards at the bottom of the mantle (Richards and Engebretson, 1992), respectively. Indeed, the most outstanding feature of the transition zone in any of the recent tomographic models (see Figure 8 of Thurber and Ritsema (2007); see also **Figure 2**) is the extensive horizontal spread of fast anomalies beneath subduction zones, which has been interpreted as a signature of stagnant slabs.

We also note in **Figure 1** that several models, for example, TX2011 and LLNL-G3Dv3, show a secondary peak in the uppermost lower mantle, just below the 660-km discontinuity. Although other models do not exhibit such a clear peak, they still show a richness of high-velocity anomaly signals in the uppermost lower mantle. This richness is an indication of

 http://dx.doi.org/10.1016/B978-0-444-53802-4.00025-7

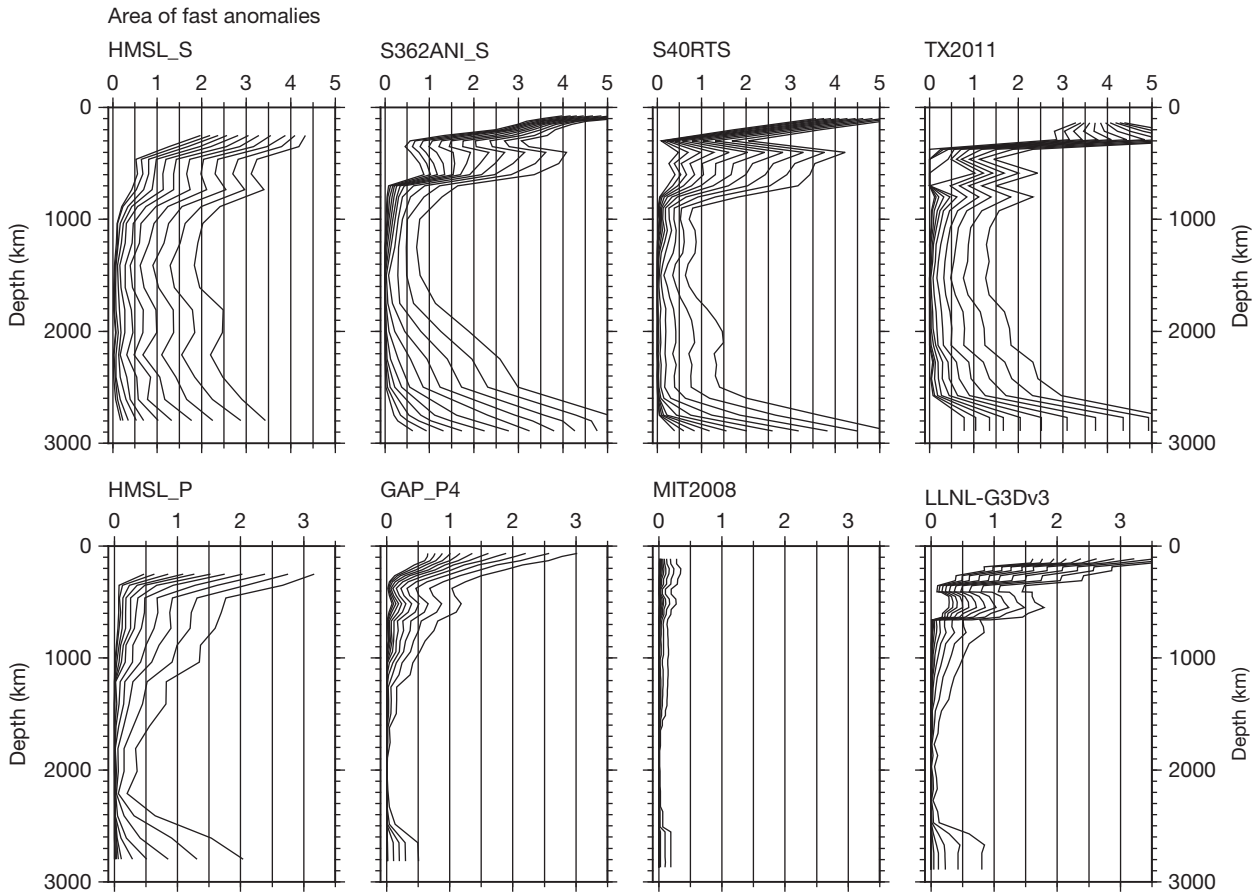

Figure 1 Depth profiles of the areal proportion of high-velocity anomalies in global tomographic models. The area at each depth is normalized so that its maximum is 4π. The 16 profiles from right to left in each diagram represent the areal proportions of velocity anomalies 0.5%, 0.6%,. . ., 1.5% higher than normal. The S-wave velocity models in the upper column are HMSL (Houser et al., 2008a), S362ANI (Kustowski et al., 2008), S40RTS (Ritsema et al., 2011), and TX2011 (Grand, 2002). The P-wave velocity models in the lower column are HMSL (Houser et al., 2008a), GAP_P4 (Obayashi et al., 2013), MIT-P08 (Li et al., 2008), and LLNL-G3Dv3 (Simmons et al., 2012). Note a difference in scale between the S-wave and P-wave velocity models.

the slabs that penetrate the 660-km discontinuity and extend subhorizontally in the uppermost lower mantle. The mantle transition zone and the uppermost lower mantle are reviewed here as two distinct reservoirs, one for downgoing slabs above the 660-km discontinuity and the other for penetrating slabs below the discontinuity. Both reservoirs are not complete in the sense that slabs eventually descend well into the deep lower mantle (Grand et al., 1997; van der Hilst et al., 1997). We hope this chapter will be useful for discussing how significant the transition zone and the uppermost lower mantle are in the whole system of mantle convection. Wen and Anderson (1995, 1997) emphasized the unique role of the uppermost lower mantle in the system of mantle convection involving surface plate motions. Another intriguing feature to be noted in **Figure 1**, although not discussed in this chapter, is the depth of the least horizontal spread of high-velocity anomalies, which is systematically different between the P-wave and S-wave velocity perturbations, approximately 1500 km for all the four S-wave velocity models but approximately 2000 km for all the four P-wave velocity models.

1.20.2 Global View of Subduction Zone Structure in the Transition Zone

1.20.2.1 Seismic Velocity Anomalies

Masters et al. (1982) were the first to show that the structural heterogeneity in the transition zone is, to the first approximation, dominated by a degree-2 pattern with high-velocity anomalies beneath the Circum-Pacific subduction zones (see Figure 9 of Dziewonski and Romanowicz, 2007). **Figure 2** shows the velocity anomaly patterns at depths of ~500 km in the mantle transition zone for the eight models corresponding to those in **Figure 1** (see also Figure 3 of Panning and Romanowicz, 2006 for S-wave velocity anomalies and supplementary Figure 29(a) of Meer et al., 2009 for P-wave velocity anomalies). The most pronounced feature at these depths, both in the S-wave and in the P-wave velocity models, is the high-velocity signals in subduction zones, the strongest in the western Pacific (the northwestern Pacific in particular) and the next strongest in South America (southern South America in particular). The Pacific plate, the largest oceanic

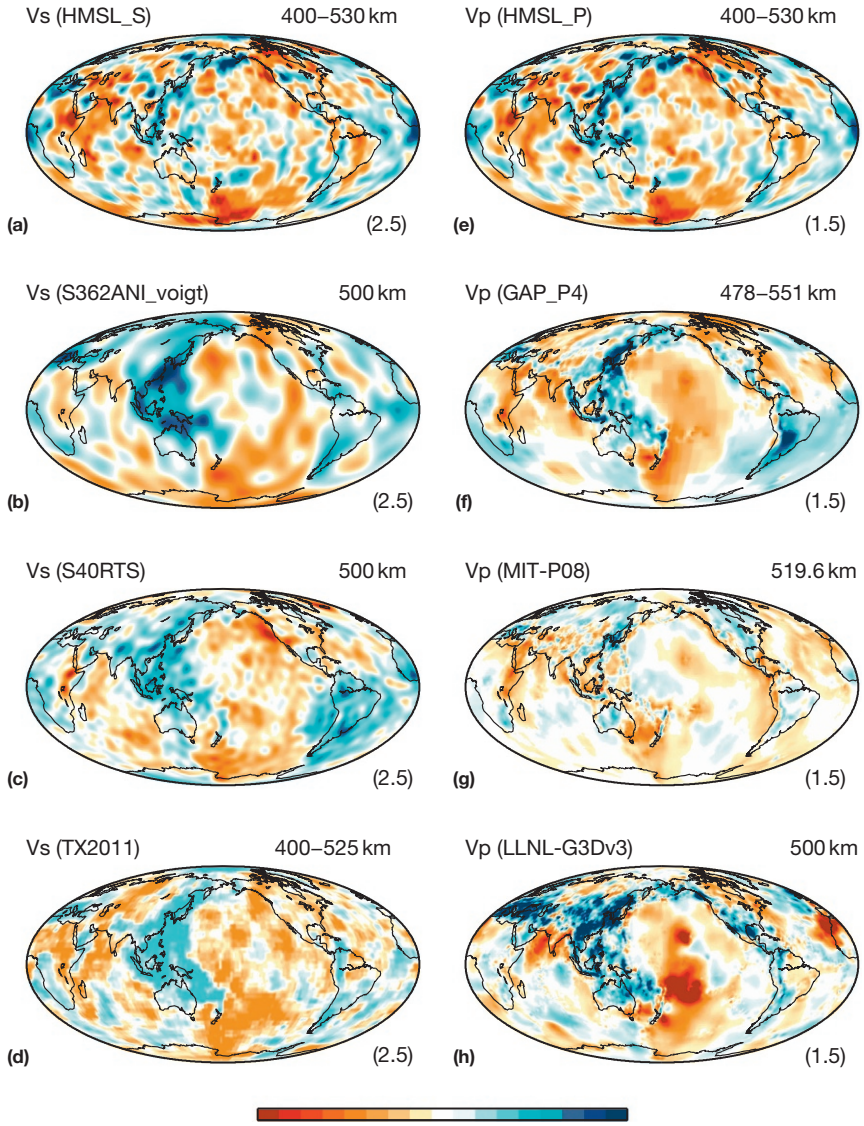

Figure 2 Depth slices in the transition zone for the four S-wave and four P-wave velocity models corresponding to those in **Figure 1**. The velocities are perturbations from the average value at the corresponding depth. The scale is ±2.5% for the S-wave velocity models and ±1.5% for the P-wave velocity models.

plate, has continued to subduct beneath the western Pacific since the late Cretaceous Period, although its spreading direction changed greatly in the early Eocene Epoch (Lithgow-Bertelloni and Richard, 1998). The Indo-Australian plate, the second largest oceanic plate, has also continued to subduct beneath the western Pacific since the fusion of the Indian plate and Australian plate in the early Eocene (Lithgow-Bertelloni and Richard, 1998). The Nazca plate and the preceding Farallon plate have continued to rapidly subduct beneath South America since the early Eocene, without intermission by, for example, ridge subduction (Lithgow-Bertelloni and Richard, 1998). Clearly, the high-velocity anomalies beneath the western Pacific and South America reflect a long history of subductions of oceanic plates. Besides the Circum-Pacific subduction zones, the Mediterranean subduction zone is marked by the anomalously fast transition zone in all eight models. This high-velocity signature reflects the long history of subduction of the Mediterranean lithosphere against the Eurasian plate since the late Cretaceous Period, including slow subduction in the first 20–30 My (Faccenna et al., 2001).

1.20.2.2 Boundary Topography

The mantle discontinuities at 410- and 660-km depths define the top and bottom of the mantle transition zone, across each of which P-wave and S-wave velocities and density increase sharply. These discontinuities are understood as the phase transition boundaries of major mantle minerals (see Stixrude and Jeanloz, 2007) that can be topographically distorted by a cold subducting slab. This subject has been reviewed by Kind and Li (2007). More recent studies include Schmerr and Thomas (2011) for Kurile, Schmerr and Garnero (2007) for South America, and Heit et al. (2010) and Gu et al. (2012) for the northwestern Pacific. Kind and Li (2007) summarized, for example, their review of the

Japan–Izu–Bonin subduction zones as follows. "The overwhelming majority of observations seem to indicate that the 660 is depressed at the Japanese subduction zone. The amount of the depression is ~50 km. The 410 remains uncertain, but there is probably no clear elevation." Kind and Li (2007) further added, "Izu-Bonin seems, beside Japan, to be a good example of a depressed 660 at a slab. The uplift of the 410 seems less clear." The depression on the order of ~50 km is likely to be the direct response of the 660-km discontinuity to the incoming slab from above. If the incoming slab bends to horizontal upon hitting the discontinuity to extend horizontally through the transition zone, we would expect a horizontal spread of the discontinuity depression, although the amount of depression may be smaller in the horizontally spreading part than in the directly downgoing part of the slab (e.g., Fukao et al., 2009).

The large lateral extent of the 660-km discontinuity depression was first observed by Shearer and Masters (1992) and Shearer (1993). **Figure 3** shows the three recent global topography maps for the 660-km discontinuity (see also Figure 6 of Kind and Li, 2007). The model of Houser et al. (2008b) (**Figure 3(a)**) is based on SS–SdS differential travel time measurements corrected for lateral heterogeneities of crustal thickness and upper mantle shear velocity, where SdS is a precursory reflection at depth d to the SS reflection at the surface. The model of Kustowski et al. (2008) (**Figure 3(b)**) is a part of the whole-mantle shear velocity model S362ANI (**Figure 2**) and was derived from the dataset that included SS-SdS differential times. The model of Meier et al. (2009) is not based on such depth phases as SdS, but relies on the sensitivities of overtone modes of Love waves and Rayleigh waves to the mantle discontinuity topography (**Figure 3(c)**). In these three models, the Circum-Pacific subduction zones are commonly characterized by long-wavelength depression of the 660-km discontinuity in qualitative agreement with the high-velocity anomaly pattern in the transition zone (**Figure 2**). Although the long-wavelength features are generally consistent among the three models, significant discrepancies are present as well, demonstrating the level of our understanding of the topography map of the 660-km discontinuity. Our understanding of the 410-km topography map is even less.

The reason for the less clear topographic feature of the 410-km discontinuity than the 660-km discontinuity may in part be the kinematically retarded olivine–wadsleyite transition across this discontinuity, which is expected to cause a narrow, wedge-like deepening of the phase boundary inside the cold slab (Kirby et al., 1996; Sung and Burns, 1976). A limited number of observational studies supporting the possible deepening of the phase boundary include travel time analyses by Iidaka and Suetsugu (1992) and Jiang et al. (2008) and a receiver function analysis by Kawakatsu and Yoshioka (2011) for the Honshu slab, a P-wave coda analysis by Kaneshima et al. (2007) for the Mariana slab, and a travel time analysis by Koper et al. (1998) for the Tonga slab. We are not yet at a stage where we can answer clearly whether the 410-km boundary inside the slab is elevated as expected for the phase transition at equilibrium or depressed as expected for the phase transition in a metastable state of olivine. The situation is quite different for the 660-km discontinuity, across which the phase transition from ringwoodite to ferromagnesian perovskite plus oxide should occur. In this case, the cold slab depresses the phase boundary at equilibrium, which may be further deepened by the retarded phase transition of ringwoodite in the cold environment (Fukao and Obayashi, 2013).

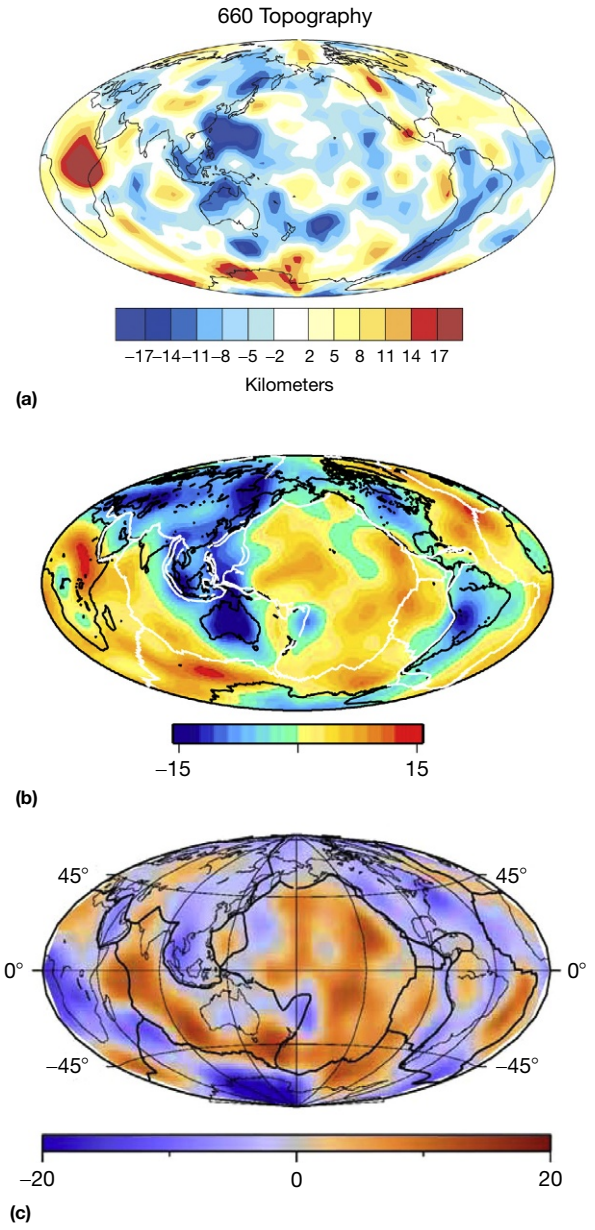

Figure 3 Deviations from the average 660-km discontinuity depth for models (a) Houser C, Masters G, Flanagan M and Shearer P (2008b) Determination and analysis of long-wavelength transition zone structure using SS precursors. *Geophysical Journal International* 174: 178–194, (b) Kustowski B, Ekström G and Dziewonski AM (2008) Anisotropic shear–wave velocity structure of the Earth's mantle: A global model. *Journal of Geophysical Research* 113 (http://dx.doi.org/10.1029/2007JB005169), and (c) Meier U, Trampert J and Curtis A (2009) Global variations of temperature and water content in the mantle transition zone from higher mode surface waves. *Earth and Planetary Science Letters* 282: 91–101. Negative values (blue) indicate that the discontinuity is deeper than average and, likewise, positive values (red) indicate that it is shallower than average.

1.20.2.3 Seismic Attenuations

The horizontal spread of high-velocity anomalies also implies the dominance of high-Q anomalies in the transition zone beneath the subduction zone. Seismic Q^{-1} is a measure of the degree of attenuation of a seismic wave. The progress

in attenuation studies has been slow because such studies typically rely on the amplitude measurement, which is affected by many factors, including determination of source mechanism, evaluation of focusing, defocusing, and scattering by structural heterogeneity, and correction for instrumental response. Such factors complicate interpretation of the measured amplitude in terms of attenuation. The current status of seismic attenuation studies of the structure of Earth is reviewed by Romanowicz and Mitchell (2007). Relatively recent global attenuation models include SW02 of Selby and Woodhouse (2002), QRLW8 of Gung and Romanowicz (2004), and QRFSI12 of Dalton et al. (2008). These models in the transition zone commonly show lower-than-normal attenuations beneath the western Pacific to eastern Asia, although the detail is quite different among the models. A counterpart of this subduction zone signal in the transition zone is the antipodal pair of high attenuation in the Pacific and in Africa, which was first demonstrated by Romanowicz (1990) from a Rayleigh wave analysis.

1.20.2.4 Seismic Anisotropy

The horizontal spread of high-velocity anomalies implies the dominance of horizontal shear flow in subduction zones, which might be detected by measuring radial seismic anisotropy in the transition zone beneath subduction zones (see Montagner, 2007). Unfortunately, resolving subduction zone characteristics of radial anisotropy from global mapping of radial anisotropy at depths near the bottom of the upper mantle remains a challenge (Ferreira et al., 2010; Kustowski et al., 2008; Lekić and Romanowicz, 2011; Panning and Romanowicz, 2006). Even the spherically averaged component of radial anisotropy is of marginal significance in this depth range, as may be understood by comparing several radial profiles of spherically averaged radial anisotropy presented in **Figure 8** of Visser et al. (2008) and Figure 11 of Panning et al. (2010). Kawazoe et al. (2013) made a high pressure/temperature deformation experiment of wadsleyte, a major constituent mineral in the transition zone, to show that if the transition zone is dominated by horizontal shear flow, one would expect a spherically averaged radial anisotropy such that $V_{SH} < V_{SV}$ (horizontally polarized S waves are slower than vertically polarized S waves).

1.20.3 Slab Signatures Above and Below the 660-km Discontinuity

In this section, the cross-sectional views of subducted slabs above and below the 660-km discontinuity, that is, in the transition zone and in the uppermost lower mantle, are reviewed. The tomographic cross-sections along 11 profiles across Kurile (KR), Japan (JP), Bonin (BN), Mariana (MR), Java (JV), Tonga (TN), Kermadec (KM), northern and southern South America (nSA and sSA), and northern and middle Central America (nCA and mCA) for two P-wave velocity models, GAP_P4 of Obayashi et al. (2013) and LLNL-G3Dv3 of Simmons et al. (2012), and for two S-wave velocity models, S362ANI of Kustowski et al. (2008) and TX2011 of Grand (2002) are examined. **Figure 4** shows the locations of these 11 profiles, which are chosen from Fukao and Obayashi (2013), who presented a number of equally spaced tomographic slices for each arc of the Circum-Pacific subduction zones. The P-wave images are scaled to ±1.5% and the S-wave images to ±2.5%.

1.20.3.1 Slab Signature in the Transition Zone

Figure 5(a)–5(c) shows the tomographic cross-sections across Japan, Bonin, and southern South America, respectively, for the two P-wave velocity models and for the two S-wave velocity models. In these figures, the 410- and 660-km depth lines define the top and bottom of the transition zone. The 1000-km depth line is added as a measure of the bottom of the uppermost lower mantle, which is not a physically distinct boundary. The resolution of a subduction zone image is different between P-wave and S-wave velocity models. In general, first arrival time-based P-wave velocity models can resolve finer structures of subduction zones. On the other hand, a more uniform resolution is anticipated by broadband waveform-

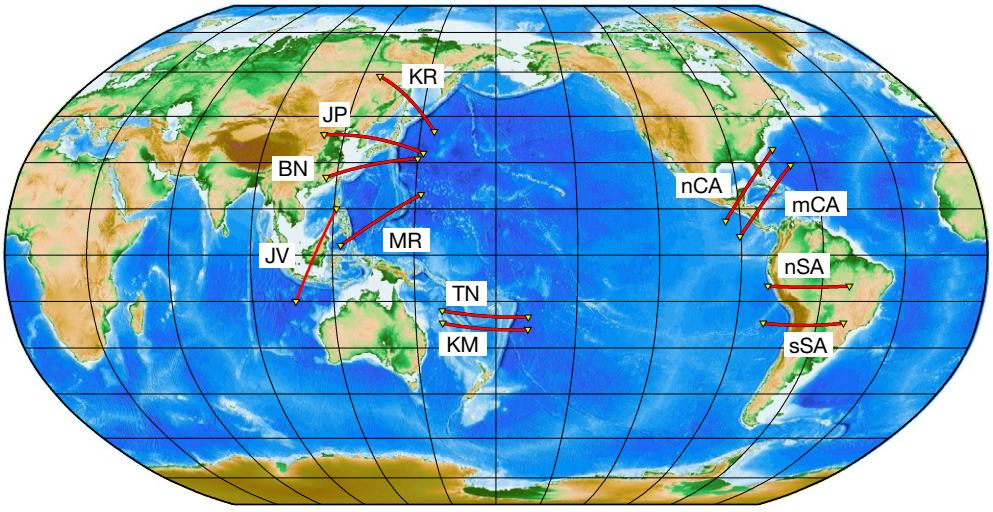

Figure 4 Location of the 11 profiles across typical subduction zones in the Circum-Pacific belt. The vertical cross-sections along these profiles are shown in **Figures 5** and **7–10**.

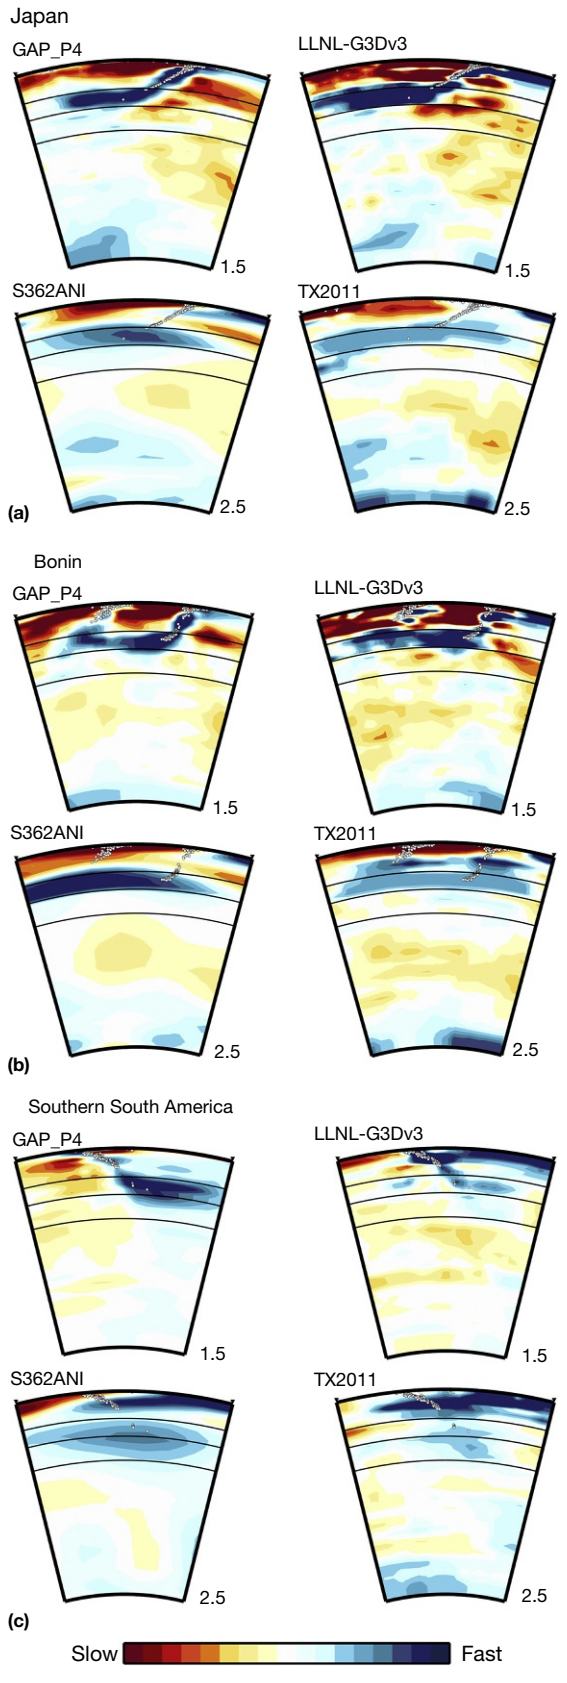

Figure 5 Cross-sections through the two P-wave and two S-wave velocity models (GAP_P4, LLNL-G3Dv3, S362ANI, and TX2011) along profiles given in **Figure 4**. Structures are shown from Earth's surface down to the core–mantle boundary beneath (a) Japan, (b) Bonin, and (c) southern South America. For reference, thin lines at 410- and 660-km depths indicate the position of the discontinuities that define the mantle transition zone. An additional line at 1000 km does not mean a physically distinct boundary, but is drawn to give a rough measure of the bottom of the uppermost lower mantle. White dots depict hypocenters of earthquakes. Mantle earthquakes are considered to occur within subducted slabs. The scale of velocity anomaly is ±1.5% for the P-wave velocity models and ±2.5% for the S-wave velocity models.

based S-wave velocity models to characterize subduction zone structures among other structural heterogeneities. Bearing such resolution differences in mind, the slab configurations are first figured out from the two P-wave velocity models, and then whether they are consistent with the images from the two S-wave velocity models examined. In **Figure 5(a)** and **5(b)**, the P-wave cross-sections across the Japan and Bonin arcs consistently show typical images of stagnant slabs above the 660-km discontinuity and the two S-wave cross-sections clearly support such an interpretation. The slab images in these subduction zones have been repeatedly revealed by P-wave tomography. See Fukao et al. (2001) for the earlier references including van der Hilst et al. (1991) and Fukao et al. (1992). More recent references include Miller et al. (2004), Huang and Zhao (2006), Li and van der Hilst (2010), van der Meer et al. (2010) and Zhao et al. (2009). Zhao et al. (2009) proposed the concept of the big mantle wedge by which they related the stagnant slabs to the widespread volcanism in eastern China. Li and van der Hilst (2010) related the horizontal spread of high-velocity anomalies in the transition zone to slab remnants since the Mesozoic Era.

Although the P-wave cross-sections across the Japan and Bonin arcs commonly show the images of stagnant slabs, the detailed slab configuration is very different. The downgoing slab beneath the Bonin arc dips more steeply and bends more sharply above the 660-km boundary than the slab beneath the Japan arc, as demonstrated in **Figure 5(a)** and **5(b)**, where the earthquake hypocenter distribution is superposed within a band 50 km wide on both sides of the cross-section plane, based on the EHB Bulletins published from the ISC (http://www.isc.ac.uk/ehbbulletin) (Engdahl et al., 1998). In the Bonin P-wave cross-sections (**Figure 5(b)**), the sharp bend of the slab image is correlated well with the bend of the deepest hypocentral distribution (Okino, et al., 1989). This correlation implies that the stagnant slab near the bending portion is brittle enough to cause earthquakes.

Figure 5(c) shows the cross-sections of the slab image of the Nazca plate along the east–west profile across Chile. Although the resolution is poorer here than in Japan and Bonin, the two P-wave velocity models consistently show the images of stagnant slab above the 660-km discontinuity. The earlier P-velocity models consistent with these images include those of Bijwaard et al. (1998) and Fukao et al. (2001). These stagnant slab images seem to be in better agreement with the fast anomaly pattern in the S-wave velocity model of S362ANI than of TX2011. Although the hypocentral distribution here shows a large gap between the intermediate-depth seismic zone and the deepest seismic zone, the P-wave velocity models seem to

suggest that the slab is continuous all the way through this seismicity gap. The deepest hypocenters extend subhorizontally in accordance with the stagnant slab images in the P-wave velocity models.

1.20.3.2 Slab Signature in the Uppermost Lower Mantle

Figure 6 shows the tomographic maps at depths of ~900 km in the uppermost lower mantle for the eight models corresponding to those in Figures 1 and 2 (see also Figure 3 of Panning and Romanowicz, 2006 for S-wave velocity anomalies and supplementary Figure 31(a) of Meer et al., 2009 for P- wave velocity anomalies). The Circum-Pacific subduction belt is still characterized by fast anomalies, both in the S-wave and the P-wave velocity models, although the intensities are, in general, weaker than those in the transition zone. The strongest anomalies in the western Pacific are now shifted southward to the Indonesia–Philippine subduction zones, and those in South America are shifted northward to northern South America.

Figure 7(a)–7(c) shows the tomographic cross-sections across Java, Kermadec, and northern South America, respectively, for two P-wave velocity models, GAP_P4 and LLNL-G3Dv3, and for two S-wave velocity models, TX2011 and S362ANI. See Fukao et al. (2001) for the earlier references for the Java slab images including Widiyantoro and van der Hilst (1996). More recent references include Replumaz et al. (2004), Li et al. (2008), van der Meer et al. (2010), and Widiyantoro et al. (2011). The cross-sections across the two P-wave velocity models and the S-wave velocity model TX2011 in Figure 7(a) indicate that the slab beneath western Java penetrates the 660-km discontinuity and then deflects subhorizontally in the uppermost lower mantle. The two P-wave velocity models show the subhorizontally deflected slab that extends not only

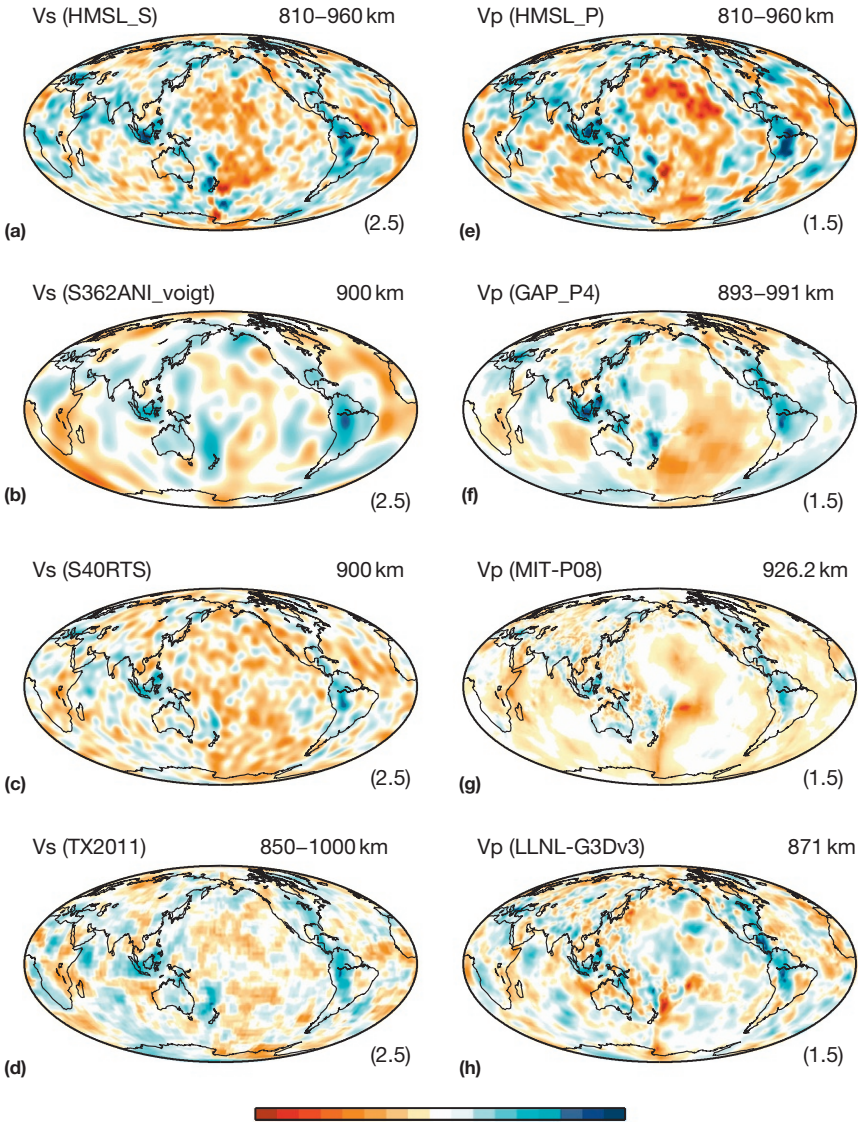

Figure 6 Depth slices in the uppermost lower mantle for the four S-wave and four P-wave velocity models corresponding to those in Figure 1. The velocities are perturbations from the average value at the corresponding depth. The scale is ±2.5% for the S-wave velocity models and ±1.5% for the P-wave velocity models.

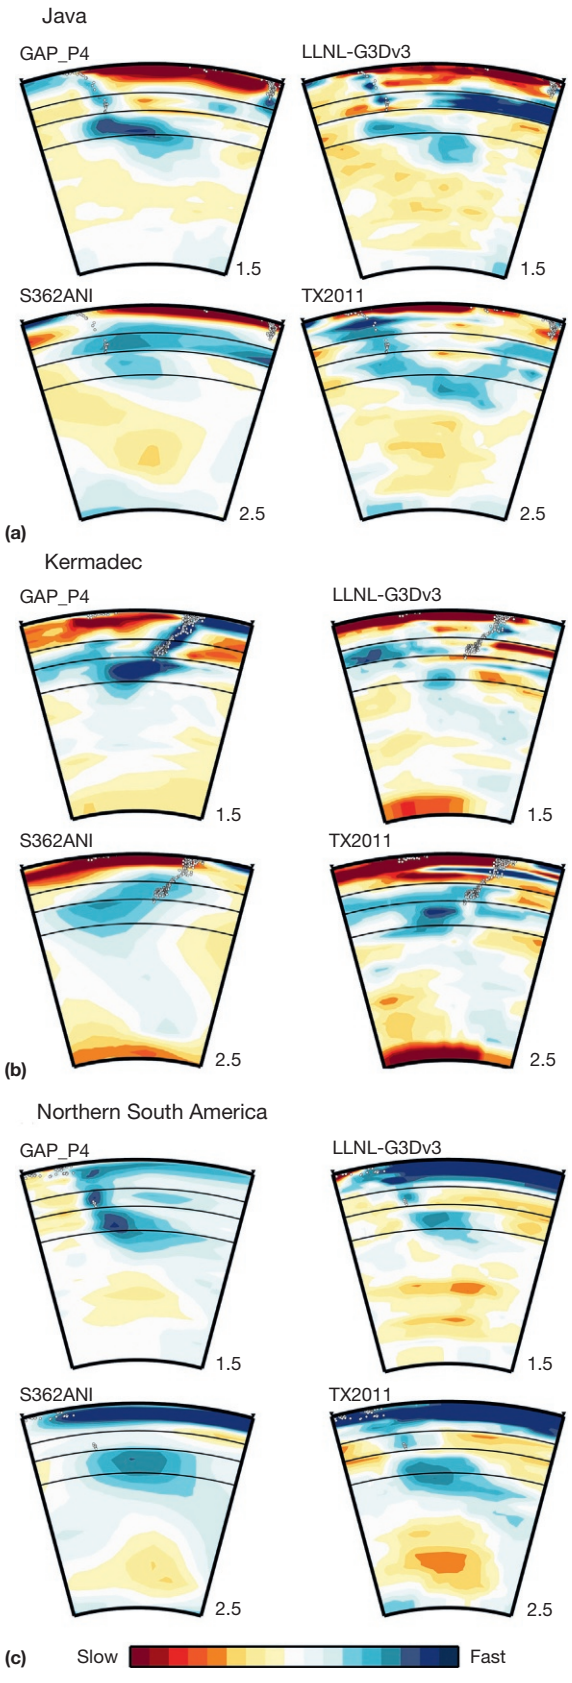

Figure 7 Cross-sections through the two P-wave and two S-wave velocity models (GAP_P4, LLNL-G3Dv3, S362ANI, and TX2011) along profiles given in **Figure 4**. Structures are shown from Earth's surface down to the core–mantle boundary beneath (a) Java, (b) Kermadec, and (c) northern South America. See **Figure 5** for other explanations.

in the forward direction but also slightly in the backward direction. Such a slab configuration may be related to the deep hypocentral distribution (at depths greater than ~500 km) that dips steeply in the slightly backward (southward) direction in agreement with the slightly backward orientation of the near-vertical compressional axes in the focal mechanisms of deep shocks (Das et al., 2000; Schöffel and Das, 1999). A slight backward spread of the slab image is also observed in **Figure 6** of Hafkenscheid et al. (2001) but not obvious in Replumaz et al. (2004) and Li et al. (2008). In **Figure 7(a)**, the two P-wave velocity models and the S-wave velocity model of TX2011 seem to indicate that the subhorizontally deflected slab begins to descend deeper, further beyond the uppermost lower mantle.

In **Figure 7(b)**, the P-wave velocity model of GAP-P4 shows an image of the subhorizontally deflected slab in the uppermost lower mantle beneath Kermadec. This slab image appears to be consistent with those of the two S-wave velocity models. These cross-sections seem to indicate that the subhorizontally deflected slab begins to descend to greater depths beyond the uppermost lower mantle. According to **Figure 4** of Schellart et al. (2009), which was constructed from the S-velocity model of Kennett and Gorbatov (2004) and the P-velocity model of Amaru (2007), this slab-related subhorizontal spread of high-velocity anomalies in the uppermost lower mantle extends further southward down to 27° S beneath the Tonga–Kermadec arc. The deepest hypocentral distribution in **Figure 7(b)** is more steeply dipping than at shallower depths. The downdip compression mechanisms of the deepest earthquakes (Alpert et al., 2010; Bonnardot et al., 2009; Brudzinski and Chen, 2005) suggest that the slab here is resisted by the surrounding mantle against its penetration across the 660-km discontinuity.

In **Figure 7(c)**, the two P-wave velocity models and the two S-wave velocity models consistently show the images of the Peruvian slab that penetrates the 660-km discontinuity, and then deflects subhorizontally in the uppermost lower mantle. The subhorizontally deflected slab seems to begin to descend deeper beyond the uppermost lower mantle. See Fukao et al. (2001) for the earlier references for the Peruvian slab images including Engdahl et al. (1995). Slab penetration is clearly imaged but subhorizontal deflection of the penetrated slab is less clear in a recent P-velocity model of Li et al. (2008). Seismic activity is very high within the penetrating slab in the proximity of the 660-km discontinuity. Although the deepest seismicity is well isolated from the shallower seismicity (see Brudzinski and Chen, 2005; Martinod et al., 2010), the tomographic cross-sections in the two P-wave velocity models seem to suggest that the slab continues through the seismicity gap between the shallow and deepest seismic zones. Earthquakes at greatest depths are of downdip compression type with steep compressional axes (average plunge = 79°; Brudzinski and Chen, 2005), suggesting that the slab here is resisted by the surrounding mantle against its steep penetration across the 660-km discontinuity.

1.20.3.3 Juxtaposed Slab Images in the Transition Zone and the Uppermost Lower Mantle

Figures 5 and 7 represent typical images of slabs deflected horizontally in the transition zone and those deflected subhorizontally in the uppermost lower mantle, respectively. The subduction zone in northern Tonga is unique in this respect, because the horizontal slab in the transition zone and the subhorizontal slab in the uppermost lower mantle may be juxtaposed in the same area. Figure 8 shows this possible juxtaposition. See Fukao et al. (2001) for the earlier references for the slab image beneath northern Tonga including van der Hilst (1995). More recent references include Hall and Spakman (2002) and Amaru (2007), which show similar slab features. Note that the deepest seismic zone here apparently splits into two, one extending at a very shallow dip and the other dipping very steeply. More detailed studies of the deep seismicity and focal mechanisms (e.g., Bonnardot et al., 2009; Brudzinski and Chen, 2005; Richards et al., 2011) suggest that the shallowly dipping seismic zone represents either the northern segment of the slab from the Tonga trench or the slab from the Vanuatu trench and that the steeply dipping seismic zone represents the southern segment of the slab from the Tonga trench. Fukao and Obayashi (2013) interpreted these two seismic zones as an indication of juxtaposition of two separate slabs, rather than a doubly thickened slab: one is stagnant above the 660-km discontinuity and the other is deflecting subhorizontally just below the discontinuity, as observed in northern Kermadec (**Figure 7(b)**). Deep shocks occurring within the stagnant slab in the transition zone are characterized by slab-parallel compression mechanisms such that the compressional axes are oriented on the average at an azimuth of 262° and an extremely shallow dip of 5° in the northern part and at an azimuth of 309° and a relatively shallow dip of 18° in the southern part (Bonnardot et al., 2009). These mechanisms imply that the stagnant slab here is resisted against its subhorizontal advance by the surrounding mantle.

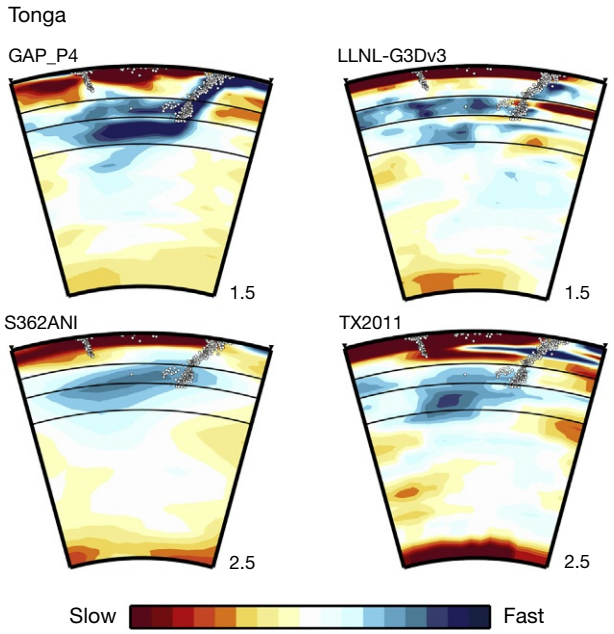

Figure 8 Cross-sections through the two P-wave and two S-wave velocity models (GAP_P4, LLNL-G3Dv3, S362ANI, and TX2011) along a profile given in **Figure 4**. Structures are shown from Earth's surface down to the core–mantle boundary beneath northern Tonga. See **Figure 5** for other explanations.

1.20.4 Seismic Images of Slab Descent Through the Transition Zone

1.20.4.1 Images of Transitional State from Slab Stagnation to Penetration

Seismic images of horizontally deflected slabs (stagnant slabs) in the transition zone (**Figure 5**) and subhorizontally deflected slabs in the uppermost lower mantle (**Figure 7**) have been overviewed so far. These images are understood to be the images of subducted slabs before and after the slab penetration. To answer the question of how a slab begins to penetrate the 660-km discontinuity and how it begins to deflect subhorizontally in the uppermost lower mantle, **Figure 9(a)** and **9(b)** shows the cross-sections across the central Kurile arc and the central Mariana arc, respectively (see Fukao et al., 1992; van der Hilst et al., 1991 for the earliest images and van der Hilst and Seno, 1993 for the early attempts to explain the along-arc variation of slab morphology). The Kurile slab is well known to be horizontally deflected above the 660-km discontinuity in southern Kurile but penetrating the discontinuity in northern Kurile, as demonstrated by **Figure 10** of Li et al. (2008), **Figure 2** of Zhao et al. (2010), and **Figure 5** of Fukao and Obayashi (2013). We may anticipate some transitional state from slab stagnation to penetration in central Kurile. In **Figure 9(a)**, the two P-wave velocity models show the images of stagnant and penetrating slabs simultaneously, although LLNL-G3Dv3 emphasizes the stagnant slab, whereas GAP_P4 emphasizes the penetrating slab. The two S-wave velocity models seem to be more consistent with LLNL-G3Dv3 than with GAP_P4.

Also well known is the fact that the steeply dipping downgoing slab is bent to sharply horizontal at depths above the 660-km discontinuity beneath the Bonin arc, whereas it penetrates the discontinuity beneath the Mariana arc, as demonstrated by **Figure 4** of Miller et al. (2004), **Figure 10** of Li et al. (2008), and **Figure 3** of Fukao and Obayashi (2013). **Figure 9(b)** shows the cross-sections across the central Mariana arc. The resolution of GAP_P4 has been improved in this region by the data from broadband ocean-bottom seismometers deployed in the Philippine Sea region (Obayashi et al., 2013). This model shows the image of the downgoing slab that penetrates the 660-km discontinuity and then enlarges horizontally in the uppermost lower mantle. It also shows the image of the stagnant slab above the discontinuity apparently detached from the downgoing slab. Such coexistence of the penetrated slab below and the stagnant slab above the discontinuity is faintly indicated in the images of V LLNL-G3Dv3 and TX2011. Model S362ANI seems to emphasize the stagnant slab more than the penetrating slab. Clearly, the lateral and vertical resolutions of the existing models are still too limited to detect the fine structure at the possible transitional stage from slab stagnation to penetration in the central Kurile and central Mariana regions.

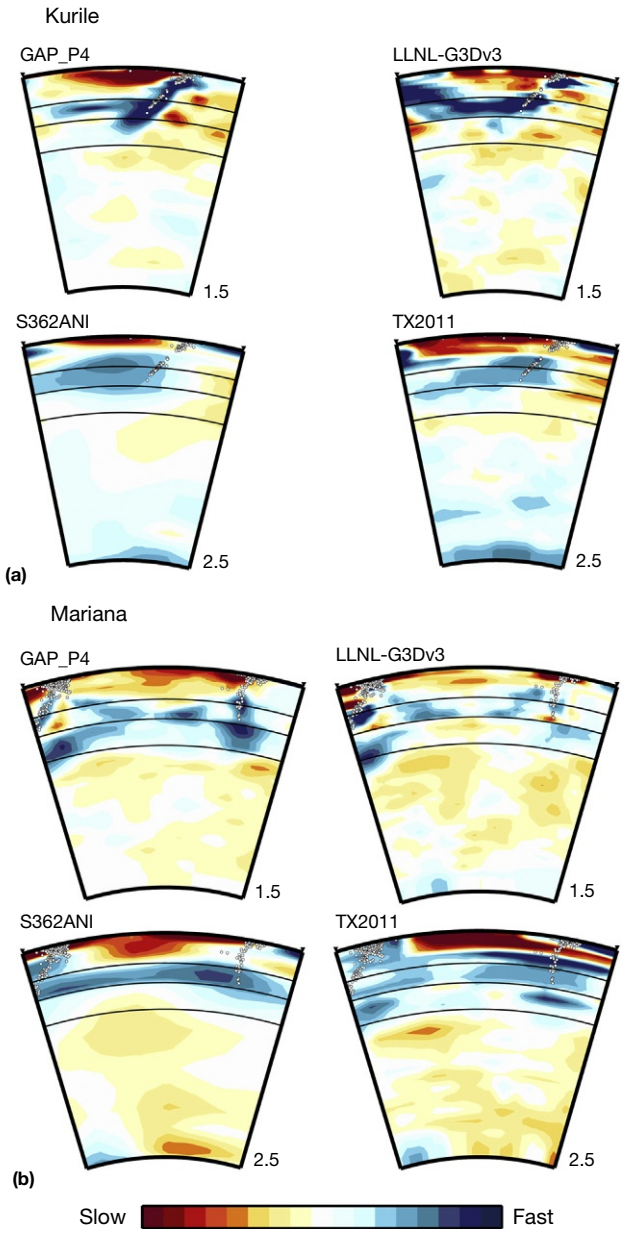

Figure 9 Cross-sections through the two P-wave and two S-wave velocity models (GAP_P4, LLNL-G3Dv3, S362ANI, and TX2011) along profiles given in **Figure 4**. Structures are shown from Earth's surface down to the core–mantle boundary beneath (a) central Kurile and (b) central Mariana. See **Figure 5** for other explanations.

1.20.4.2 Signature of Subducted Crust Materials in the Penetrating Slab

Some observational evidence indicates that a penetrating slab has fragments of subducted crust materials within it. Niu et al. (2003) detected an ~10-km thick S-to-P reflector at a depth of ~1150 km beneath the northern Mariana arc, using a Japanese short-period seismic network. They interpreted this reflector as a fragment of the oceanic crust internally displaced to the bottom of the penetrating slab. Kaneshima (2003) detected S-to-P scatterers at depths of 700–900 km beneath the central Mariana arc, using two short-period seismic arrays in the United States. All the scatterers, including those detected by Krüger et al. (2001), were located inside the deformed body of the penetrating slab. Kaneshima (2009) detected S-to-P scatterers in a depth range of 800–1000 km beneath the northern Kurile arc. He located the scatterers near the bottom of the enlarged body of the penetrating slab and interpreted them as the remnants of subducted oceanic crust. Rost et al. (2008) used off-great-circle-path precursors to PP-waves (P-waves reflected off the surface once) recorded by a Canadian short-period seismic array to detect P-to-P scatterers. They showed that these scatterers are located mostly at depths shallower than 1000 km and in large part in the Mariana subduction zone. Rost et al. (2008) interpreted these scatterers as being from the

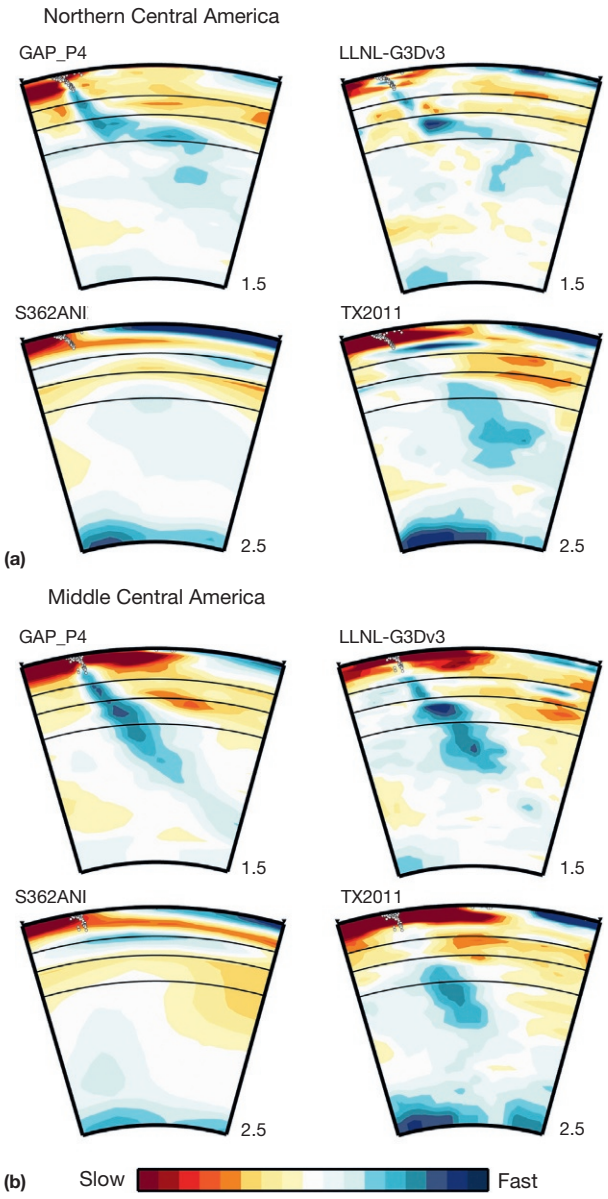

Figure 10 Cross-sections through the two P-wave and two S-wave velocity models (GAP_P4, LLNL-G3Dv3, S362ANI, and TX2011) along profiles given in **Figure 4**. Structures are shown from Earth's surface down to the core–mantle boundary beneath (a) northern Central America and (b) middle Central America. See **Figure 5** for other explanations.

paleo-Moho (the Moho is the boundary between the crust and the mantle) of the deeply subducted slabs. Although they did not show where these scatterers are located relative to the penetrated slab, all the other studies cited earlier located fragments of the subducted crust within or at the bottom of the penetrating slab rather than at the top. This location suggests that slab penetration and subsequent processes are associated with severe deformation within the slab. The penetrated crust may no longer be a coherent unit at the top of the slab.

1.20.4.3 Images of Slab Descent to the Deep Lower Mantle

The Central American subduction zone is the best place to observe images of slab descent all the way through the transition zone, the uppermost lower mantle, and the deep lower mantle. Tomographic images of the deeply subducted slab under this region have been repeatedly reported (Grand, 2002; Li et al., 2008; Ren et al., 2007; see Fukao et al. (2001) for the earlier references including van der Hilst et al., 1997 and Grand et al., 1997). **Figure 10(a)** and **10(b)** shows the cross-sections across the northern and middle Central American arcs, respectively. In **Figure 10(a)**, GAP_P4 and LLNL-G3Dv3 show slab configurations remarkably similar to each other. The downgoing slab penetrates the 660-km discontinuity, thereby deflecting to horizontal below the discontinuity, and is then apparently folded down into the deeper mantle. This deeper part of the slab is emphasized more in TX2011 than in the two P-wave velocity models. In **Figure 10(b)**, the slab configurations shown by GAP_P4, LLNL-G3Dv3, and TX2011 are remarkably similar to each other (see also Li et al., 2008). The slab extends almost straight through the intermediate-depth seismic zone downdip to mid-mantle depths of approximately 1500 km. Fukao and Obayashi (2013) interpreted the slab configurations in **Figure 10(a)** and **10(b)** as those at the relatively earlier and later stages of deep slab subduction.

1.20.5 Summary

The mantle transition zone acts as a (temporal) reservoir for subducting slabs of lithospheric plates, as typically observed in Japan, Bonin, and southern South America (**Figure 5**). Increasing evidence suggests that the uppermost lower mantle acts as another (temporal) reservoir for subducting slabs, although its bottom is defined only loosely. The typical subduction zone of this type includes Java, Kermadec, and northern South America, where the penetrated slab is deflected subhorizontally in the uppermost lower mantle (**Figure 7**). One can observe the juxtaposition of a horizontal slab above the 660-km discontinuity and a subhorizontal slab below the discontinuity beneath the northern Tonga arc (**Figure 8**). In general, slabs in central Kurile and central Mariana are not well resolved, but the images give some idea of how the transition from slab stagnation to penetration occurs (**Figure 9**). Some evidence indicates that slabs trapped in the deeper reservoir are severely deformed internally so that the subducted oceanic crust is fragmented into scattered pieces.

A remarkable correlation exists between the slab image in the transition zone and the deepest hypocentral distribution (Fukao and Obayashi, 2013). The dip of the deepest hypocentral distribution often deviates from the dip of the major seismic zone. In the case of a horizontally deflected slab above the 660-km discontinuity, the deepest hypocentral distribution tends to dip more gently than the shallower portion of the seismic zone (see the cross-sections across Bonin and Chile in **Figure 5**). In the case of a subhorizontally deflected slab below the discontinuity, the deepest hypocentral distribution tends to dip more steeply than the shallower part of the seismic zone (see the cross-sections across Java, Kermadec, and Peru in **Figure 7**). This is also the case of a downgoing slab

beginning to penetrate the discontinuity or beginning to spread laterally below it (see the cross-sections across central Kurile and central Mariana in Figure 9). In the case where the slab images suggest juxtaposition of the horizontal slab above the 660 and the subhorizontal slab below the 660, the deepest hypocentral distribution apparently splits into two, one dipping very gently and the other dipping very steeply (see the cross-section across Tonga in Figure 8).

Downgoing slabs tend to be deflected horizontally in the transition zone, and penetrated slabs tend to be deflected subhorizontally. The transition zone and the uppermost lower mantle are thus two distinct reservoirs of subducted slabs. Together they constitute a chain of slab reservoirs around the Circum-Pacific; however, both allow slab leakage from the bottom. The deeply descending slab images beneath Central America (Figure 10) may be understood as an extreme case of slab leakage from the bottom of the uppermost lower mantle well into the mid-lower mantle. While either the transition zone or the uppermost lower mantle serves as a slab reservoir, only the former acts as a reservoir of water. The water solubility in the major mineral of the transition zone is ~3.3 wt% (wadsleyite) to ~2.6 wt% (ringwoodite), whereas it is only <30 ppm (Mg-perovskite) to <100 ppm (ferropericlase) in the major mineral of the uppermost lower mantle (Litasov et al., 2006). Even if the slab in the transition zone contains a significant amount of water, water should be expelled from the slab upon penetration across the 660-km discontinuity. At present, however, there is no consensus on how and to what extent water is carried down into the transition zone with the subducting slab (Jacobsen and van der Lee, 2006; Kawakatsu and Yoshioka, 2011; Meier et al., 2009; Tonegawa et al., 2008).

Acknowledgments

We would like to thank the editors (Barbara Romanowicz and Adam Dziewonski) and the reviewer (Rob van der Hilst) for their comments, which were very useful for improvement of the manuscript.

Glossary

410 discontinuity Seismic discontinuity at 410 km depth in global average, mainly caused by phase transition from olivine to spinel.

520 discontinuity Seismic discontinuity near 520 km depth, observed at many places on Earth, but not laterally continuously.

660 discontinuity Seismic discontinuity at 660 km depth in global average, caused by spinel to magnesiowuestite–perovskite phase transition.

Asthenosphere Low-viscosity weak layer below the lithosphere.

EarthScope with USArray Large projects to study the North American lithosphere.

GEOFON Global seismic network of the GFZ Potsdam, Germany, and international partners.

GEOSCOPE Global seismic network of the IPGP Paris, France.

Gutenberg discontinuity Seismic discontinuity with a decrease of velocity downward, top of low-velocity zone. May be lithosphere–asthenosphere boundary in oceanic regions.

Hales discontinuity Seismic discontinuity in the mantle lithosphere.

Hi-net High-sensitivity seismograph network in Japan.

INDEPTH International Deep Profiling of Tibet and the Himalaya

IRIS Global seismic network of US universities and US Science Foundation.

LAB Lithosphere–asthenosphere boundary; boundary between high-viscosity lithosphere and low-viscosity asthenosphere.

 http://dx.doi.org/10.1016/B978-0-444-53802-4.00017-8

Lehmann discontinuity Seismic discontinuity, supposed to be the bottom of the asthenosphere.
Lithosphere Elastic uppermost layer of the Earth, defined by its mechanical properties; lithospheric plates move over great horizontal distances.
MLD Recently discovered midlithospheric discontinuity in cratons near 100 km depth with velocity decrease downward.
Moho Mohorovičić discontinuity, crust–mantle boundary, seismically defined.
ORFEUS Observatories and Research Facilities for European Seismology, the Netherlands.
P′P′ Abbreviation of PKPPKP, a P phase bottoming in the core with one reflection at the surface.
PP P phase with one reflection at the surface.
Ps P-to-S converted wave.
Receiver functions P-to-S converted phases in the coda of P, or S-to-P conversions as precursor of S, diagnostic for structure beneath a seismic station.
ScS S wave reflected from the core–mantle boundary.
Sp S-to-P converted wave.
SS S phase with one reflection at the surface.

1.21.1 Introduction

When Ernst von Rebeur-Paschwitz recorded in Potsdam, Germany, the first teleseismic earthquake, he immediately recognized the importance of his discovery for illuminating the Earth's interior (von Rebeur-Paschwitz, 1889). He suggested that a global network of seismographs should be installed and the data should be evaluated by seismologists. This is still today a very modern idea, although we have achieved much since then with the construction of the Global Seismographic Network and the free exchange of data. The evaluation of the first seismic records showed that the Earth has an onion shell character with crust, mantle, and outer and inner core, separated by seismic discontinuities. The increase of seismic data led later to the discovery of more seismic discontinuities in the upper mantle; the Gutenberg, the Hales, and the Lehmann discontinuities; and, especially important, the discontinuities at about 410, 520, and 660 km depth (called simply the '410,' '520,' and '660'), and perhaps even more less clear ones. The exact knowledge about these discontinuities, their distribution, their topography, their nature, or their sharpness sets boundary conditions for mantle dynamics or petrology. For plate tectonics, the concept of rheological layers (lithosphere and asthenosphere) became important. Immediately, the question arises: How can these mechanical plate definitions be confirmed with seismological observations? What is the seismic appearance of the lithosphere–asthenosphere boundary (LAB)? Since seismology is in first order in observational science, the increase of data can bring an increase of knowledge. Therefore, the seismic networks are continuously densified (e.g., EarthScope with USArray) in order to produce more detailed images of the Earth's interior. It is easily foreseeable that these new data will lead to a wealth of new discoveries about the dynamics of our planet.

We review the global structure of the major seismic discontinuities in the upper mantle. The emphasis of our study is the seismic observations. We are mainly discussing seismic methods that are sensitive to discontinuities rather than to gradual velocity changes, like seismic tomography. The well-known discontinuities at about 410 and 660 km average depth globally are primarily focused upon. The Moho, separating the upper mantle from the crust, is not discussed here (see **Chapters 1.11**, **1.12**, **1.13**, **1.14**, and **1.15**). Between the Moho and 410, a number of additional discontinuities are reported, of which we will only treat the relatively well-established and pervasive ones, although they are all much less clear than the discontinuities so far mentioned. These discontinuities include the Gutenberg discontinuity, which is frequently identified with the LAB between about 100 and 200 km depth, the Hales discontinuity at 80 km depth, and the Lehmann discontinuity at the base of the asthenosphere at 220 km depth. Except for the LAB, all mentioned discontinuities are seismologically defined. The LAB was originally defined mechanically by postglacial rebound observations (see **Chapters 6.02** and **6.03**). Seismologists are trying to identify this discontinuity in seismic data. In the course of plate tectonics, the LAB gained additional significance since it was suggested that lithospheric plates move over large horizontal distances with the LAB as a shear zone. Since the LAB is so far only poorly observed seismologically and then mainly by low-resolution long-period surface waves, it is usually assumed that it is a broad transition zone rather than a sharp seismic discontinuity. In recent times, receiver functions have sharpened our view at the LAB.

Wide-angle observations have been the fundamental seismic tool for detecting the upper-mantle discontinuities (see **Chapters 1.04** and **1.05**). This technique is however less suited for determining their small-scale topography, because the lateral part of the travel path of wide-angle rays is several times longer than the vertical part. Steep-angle techniques (see **Chapter 1.08**), which are more suited for determining small-scale topography of the mantle discontinuities, include ScS reverberations (e.g., Revenaugh and Jordan, 1987, 1991a,b); SS, P′P′, and PP precursors (e.g., Adams, 1968, 1971; Bolt, 1970; Engdahl and Flinn, 1969; King et al., 1975; Shearer, 1991, 1993; Whitcomb and Anderson, 1970; Zheng and Romanowicz, 2012); and Ps and Sp conversions at the discontinuities (receiver functions, e.g., Bath and Stefansson, 1966; Benz and Vidale, 1993; Chevrot et al., 1999; Faber and Müller, 1980; Li et al., 2003a; Stammler et al., 1992; Vinnik, 1977; Xu et al., 1998; see **Figure 1** for ray paths of such phases). All these phases are small secondary phases in front of or after a main phase like P, S or PP, P′P′, SS, or ScS (see **Chapter 1.20**). Ps or Sp conversions or reflections of local high-frequency subduction zone earthquakes may be used to map the topography of the 410 and 660 with very high resolution (see ray paths in **Figure 2**).

At the beginning of seismological research, all data have been analog. Processing of the data, even simple plotting at the

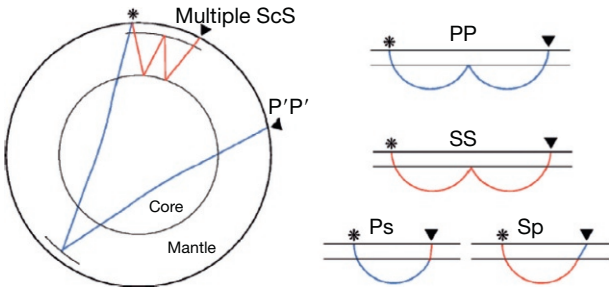

Figure 1 Ray paths of teleseismic phases frequently used to study mantle discontinuities. They include ScS reverberations reflected at upper- or lower-mantle discontinuities; P′P′ (PKPPKP) precursors from upper-mantle discontinuities; SS and PP precursors and Ps and Sp conversions at upper-mantle discontinuities (receiver functions).

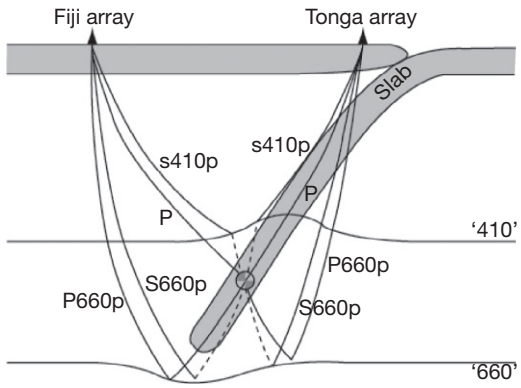

Figure 2 Reflected and converted rays of locally recorded subduction zone earthquakes. Such high-frequency data result in high-resolution imaging of the mantle discontinuities near subduction zones. Reproduced from Tibi R and Wiens DA (2005) Detailed structure and sharpness of upper discontinuities in the Tonga subduction zone from regional broadband arrays. *Journal of Geophysical Research B: Solid Earth* 110(6): 1–14, Figure 2.

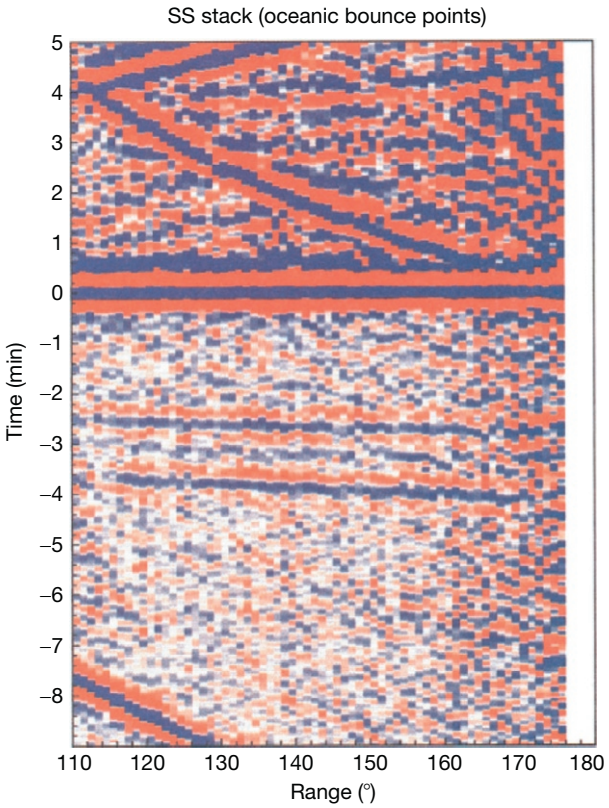

Figure 3 Global stacks of SS waveform data. Time versus range image showing SS (at 0 min) and its precursors (between about −2 and −4 min) at 410, 520, and 660 km depth obtained by stacking long-period seismograms. Reproduced from Shearer PM (1996) Transition zone velocity gradients and the 520-km discontinuity. *Journal of Geophysical Research* 101: 3053–3066, Plate 1.

desired scale, was difficult. Still, the major one-dimensional (1D) structure of the Earth was resolved with such data. In the last decades, digital techniques, however, have made a rapid development. Since weak seismic signals are more and more used, which are hardly visible in individual seismograms, delay-and-sum techniques, known as stacking in array technology, are introduced in seismology. Array techniques require large amounts of data. The processing steps applied now include simple rotation of the components for separation of the different wave types, deconvolution or correlation techniques, or migration from the time domain into depth sections. Ps conversions are increasingly used (Langston, 1979; Vinnik, 1977). In crustal studies, they are known under the name 'receiver functions.'

Ps conversions are also often used for observations of the discontinuities at 410 and 660 km depth below single broadband stations or arrays of broadband stations. Long-period SS precursors, which are reflected at the midpoint between source and receiver at upper-mantle discontinuities, are also frequently utilized. They are especially useful for global mapping of the discontinuities at 410, 520, and 660 km depth (see Figure 3). An important advantage of SS precursors is that they provide information about oceanic regions where few stations are located.

Secondary peg-leg multiples of ScS and its reverberations are very useful (see Figure 4 for a data example). More recently, Sp conversions (incident teleseismic S waves converted to a P wave at a discontinuity below a station) have also proved to be successful in observing boundaries in the upper mantle.

There are two types of seismic data that are mainly utilized for studies of the upper-mantle discontinuities. The first type stems from the permanent global seismic networks (Incorporated Research Institutions for Seismology, IRIS, see Butler et al. (2004); GEOFON, see Hanka et al. (2000); GEOSCOPE, see Romanowicz et al. (1991); or ORFEUS, see http://www.orfeus-eu.org/) and many other contributing stations. These networks together have a global coverage but still have a relatively low density of station distribution in many regions. This is especially true for oceanic areas. Data from these networks can result in relatively low-resolution global images. Oceans are only sampled with island stations, which are highly exceptional places, not typical of the large-scale oceanic mantle. Permanent or temporary ocean-bottom installations are very expensive and technically difficult and for this reason very rare. The second type of data stems from relatively short-term deployments of much denser networks (see Chapter 1.14). They have only local or regional distribution but allow much higher-resolution

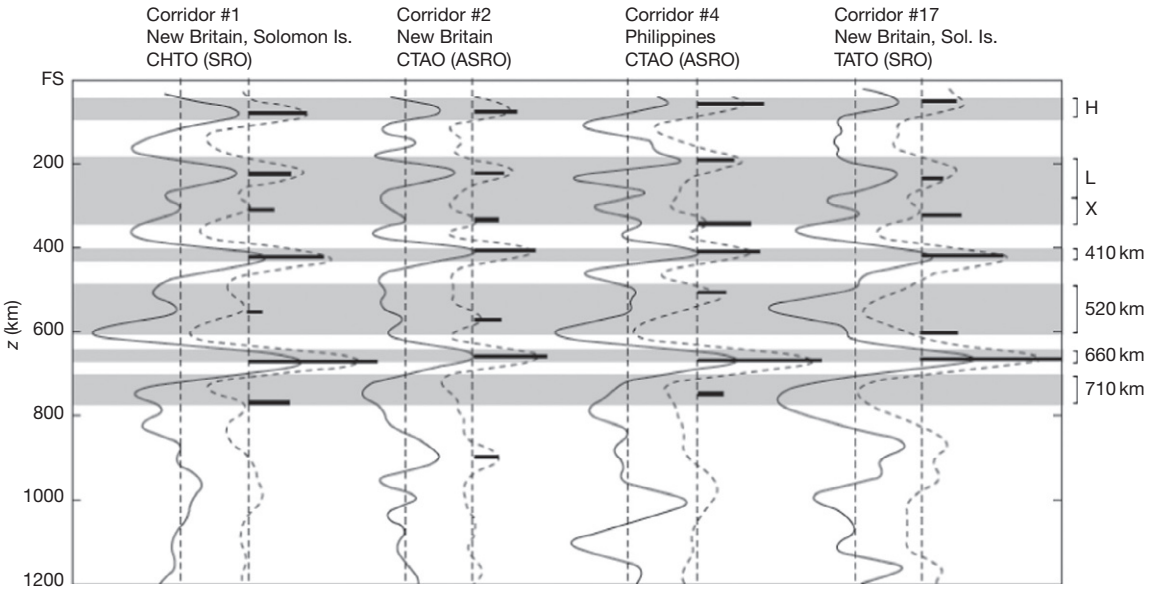

Figure 4 Observed (solid lines) and synthetic (dashed lines) ScS reverberations from a number of upper-mantle discontinuities along several great circle paths. Reproduced from Revenaugh JS and Jordan TH (1991b) Mantle layering from ScS reverberations. 3: The upper mantle. *Journal of Geophysical Research* 96: 19781–19810, Figure 3.

images. The previously mentioned permanent networks operate open stations allowing unrestricted near-real-time access to their data by any user. Most temporary networks also make their data freely available after some time. Therefore, a rapidly increasing amount of high-quality seismic data is available for global studies. This policy of free data access is of great advantage for international science and the first examples provided by the IRIS and PASSCAL projects, as the large data producers, cannot be overestimated.

1.21.2 The Mantle Transition Zone

1.21.2.1 Global Transition Zone Structure

All modern global reference Earth models show a sudden increase of the velocities of the elastic waves and densities near 410 and 660 km depth (e.g., the PREM, Dziewonski and Anderson, 1981, or the IASP91 global reference model, Kennett and Engdahl, 1991). This region of the mantle is called the transition zone between the upper and lower mantle. Earlier Earth models (Gutenberg, 1959; Jeffreys and Bullen, 1940) indicate changes in the velocity gradients at these depths, without resolving first-order discontinuities, based on observations of slowness changes and increasing P wave amplitudes at about 20° epicentral distance (Byerly, 1926; Jeffreys, 1936). More intensive seismic wide-angle controlled source and earthquake source studies began in the 1960s, leading to better data quality; hence, the two major global seismic discontinuities were discovered near 410 and 660 km depth (e.g., Ibrahim and Nuttli, 1967; Johnson, 1967; Julian and Anderson, 1968; Kanamori, 1967; Niazi and Anderson, 1965). In the following years, many wide-angle studies were undertaken and regional upper-mantle models were derived for continental and oceanic areas (e.g., Walck, 1984; or summarized by Nolet et al., 1994 and Gaherty et al., 1996; see **Chapter 1.07**). The computation of theoretical seismograms has been an essential tool for modeling the waveforms at the travel-time triplications (e.g., Helmberger, 1968; Helmberger and Wiggins, 1971).

Both discontinuities have been interpreted as pressure- and temperature-induced phase changes in the olivine system (e.g., Anderson, 1967; Anderson and Bass, 1986; Bass and Anderson, 1984; Bina and Wood, 1986; Birch, 1952; Green and Liebermann, 1976; Green and Ringwood, 1967; Ito and Takahashi, 1989; Jeanloz and Thompson, 1983; Lees et al., 1983; Liu, 1976; Ringwood, 1969; Shim et al., 2001; see **Chapter 2.06**). It has, however, also been suggested that compositional changes may occur around these depths (e.g., Irifune and Isshiki, 1998). If the 410 and 660 are olivine phase boundaries, then lateral temperature changes would cause topography of both discontinuities. From the estimated Clapeyron slopes of both discontinuities, it is expected that a 100 K temperature variation would change the depths of the 410 and 660 by about 8 and 5 km, respectively (Bina and Helffrich, 1994). The Clapeyron slopes have opposite signs (410 positive and 660 negative), so a 100 K higher temperature should reduce the transition zone thickness by about 13 km and a 100 K lower temperature should thicken the transition zone by about the same amount. Thus, the topography of the upper-mantle discontinuities, or better the thickness of the transition zone, should indicate the lateral distribution of hot and cold regions in the transition zone. The depths of the 410 and 660 discontinuities should be anticorrelated if the effect of temperature dominates and the temperature at the 410 correlates with that at 660 (Revenaugh and Jordan, 1989, 1991a). Such thinner and thicker transition zone regions could play an important role in revealing global mantle circulation, as they could distinguish upwelling and downwelling material. However, it should be kept in mind that the topography of the 410 and 660 could also be modified by other influences (e.g., chemistry or garnet phase transitions; see Anderson (1989)).

Topography could also be caused by metastable olivine below 410 km depth in subduction zones (Kirby et al., 1996).

Images of the global transition zone thickness should be able to answer several questions. The first one should be to verify the reality of the model of olivine phase transformations as the cause of the discontinuities at 410 and 660 km depth and also to verify laboratory values of the Clapeyron slopes of both discontinuities. This could be done if global anticorrelation of both discontinuities would be observable. The second question would be to confirm possible locations of hot and cold material in the transition zone in regions where we also have other evidence for hot or cold material (e.g., from tomography or earthquake locations in subduction zones or below postulated plumes). A third question would be to contribute to the problem of the deep roots of continents, which may affect even the transition zone (Jordan, 1975).

Ps and Sp conversion techniques sample the upper-mantle structure within a radius of several hundred kilometers around a seismic station. Precursor techniques of surface-reflected phases, such as PP or SS, sample the midpoints between epicenters and receivers. Precursor techniques allow a better global distribution of sampling points, reaching locations without stations or earthquake sources. They have the drawback of being associated with maximum travel-time phases, which raises the issue of possible contamination by small-scale, off-great-circle-path structure. This and related questions have been discussed by Neele et al. (1997), Shearer et al. (1999), Neele and De Regt (1999), and Chaljub and Tarantola (1997). On the other hand, converted phases, which are minimum travel-time phases, allow better resolution, in principle, due to their smaller Fresnel zones. Their global sampling is poorer, however, because they are restricted to near-station or earthquake locations. Liu (2003) pointed out possible problems caused by attenuation for detecting upper-mantle signals. Secondary phases like Sp or Ps conversions, or SS or PP precursors, are usually very weak phases, so summation must be used to improve the signal-to-noise ratio. In the case of conversions, frequently, data from one station are summed. If stations are sufficiently closely spaced, traces with nearby conversion points may be summed (common conversion point summation). Sp conversions sample a larger region than Ps conversions because of the ray paths involved. In the case of SS or PP precursors, traces with close reflection points are summed (common reflection point summation). An et al. (2007), Gu et al. (2009), and Gu and Sacchi (2009) applied the Radon transform method to SS precursors.

The 410 and 660 have been detected in multiple reflections of S waves from the core–mantle boundary (ScS reverberations) by Revenaugh and Jordan (1987, 1991a) in the western Pacific. They found a negative correlation of both discontinuities with about a 20 km topography. In an early paper, Wajeman (1988) stacked PP precursors from earthquakes in Japan, recorded in Europe, with bounce points below northern Eurasia. The first truly global map of the 660 was obtained by Shearer and Masters (1992) from SS precursors. A significant result was the deepening of the 660 around the Pacific. Shearer (1993) published the first maps of both discontinuities, the 410 and 660, from SS precursors. A similar study was done by Gossler and Kind (1996), who suggested a correlation of the transition zone thickness with the ocean–continent distribution at the Earth's surface, which would imply a relation of the continental roots and the transition zone. Flanagan and Shearer (1998a) found a thinned transition zone in the Pacific and a thickened one at the Pacific subduction zones. No ocean–continent correlation with transition zone thickness was concluded by Gu et al. (1998) in SS precursors. They observed, however, a discontinuity at 520 km depth below oceans, but not below continents. An ocean–continent correlation with the transition zone thickness was also not confirmed by Flanagan and Shearer (1999) in PP precursor data. They found a 30 km global topography of the 410. A slightly thicker transition zone below continents than below oceans was found by Gu and Dziewonski (2002) in a global SS precursor study (see **Figure 5**). A significant change of the depth of the 410 at subduction zones was not observed by Flanagan and Shearer (1998b) using precursors of depth phases from the 410 from deep subduction zone earthquakes. Helffrich (2000, 2002) studied and reviewed the global transition zone. An astonishing observation was made by Estabrook and Kind (1996) who demonstrated that PP precursors from the 660 are globally not observed, in contrast to the prediction by the IASP91 global reference model and to the clearly observed PP precursors from the 410 (see **Figure 6**). Shearer and Flanagan (1999) modeled velocity and density jumps across the 660 to explain the missing PP precursors from the 660. Deuss et al. (2006) observed PP precursors of the 660 in some regions. Thomas and Billen (2009) also observed the 660 in PP

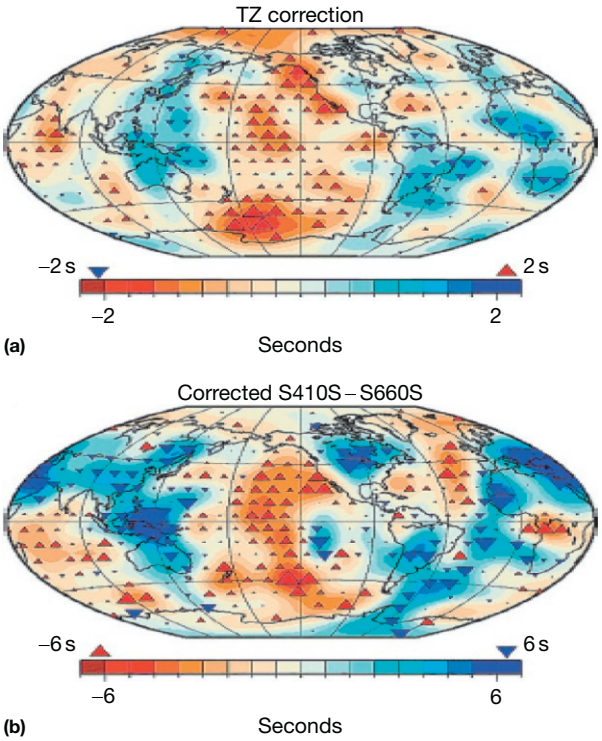

Figure 5 (a) Colored background: velocity perturbations from tomography at 550 km depth. Triangles: computed corrections for SS precursors using the tomography model. (b) Global differential times of SS precursors from the 410 to 660 discontinuities, corrected with data in (a). Reproduced from Estabrook CH and Kind R (1996) The nature of the 660-kilometer upper-mantle seismic discontinuity from precursors to the PP phase. *Science* 274: 1179–1182, Figure 1.

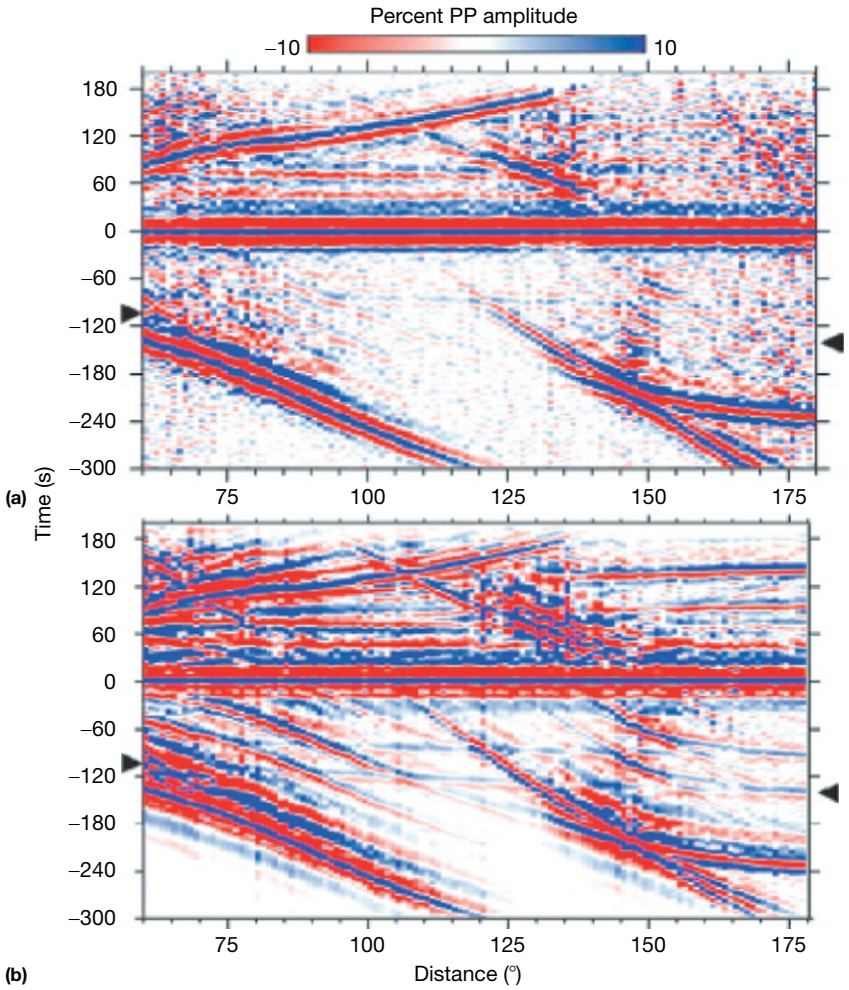

Figure 6 (a) Global stacks of PP waveforms showing PP (at 0 s) and precursor from the 410 (at about −70 s). The precursor from the 660 is missing in the data. (b) Corresponding synthetic seismograms for the IASP91 global reference model. This model (and other reference models) predicts a precursor at the 660. A model explaining the missing 660 precursor should have less contrast in P velocity. Reproduced from Gu YJ and Dziewonski AM (2002) Global variability of transition zone thickness. *Journal of Geophysical Research* 107(7): 2135. http://dx.doi.org/10.1029/2001JB000489, Figure 9.

precursors in the southwest Pacific. Day and Deuss (2013) compared observations of P′P′ and PP precursors from the 660.

Different flow patterns below and above the 660 have been derived by Gu et al. (2001b). A correlation between tomographic velocities in the transition zone and its thickness from Ps conversions was found by Lebedev et al. (2002b, 2003). Gu et al. (2003) inverted simultaneously SS precursors and tomographic velocities for mantle transition zone structure (see **Figure 7**). A comparison of Ps conversions and SS precursors below hot spots was made by Li et al. (2003a,b). They found a thinned transition zone below many hot spots and a plume width of <200 km in diameter (see **Figure 8**). In a joint inversion of PP and SS precursors, Chambers et al. (2005a,b) found an uplifted 410 beneath cratons in agreement with the results of Gu et al. (1998). Lawrence and Shearer (2006a,b, 2008) did comprehensive global studies in comparison with tomography results. Anticorrelation of SS precursors from the 410 and 660 was found by Houser et al. (2008). Andrews and Deuss (2008) and Deuss (2009) observed doublet structures of the 660 in many regions and reviewed SS and PP precursor studies. With SS precursors, Heit et al. (2010) found along a profile from the Aleutians to Tibet a thickened transition zone below the Pacific subduction region and below northern Tibet. Das Sharma et al. (2010) suggested a relation between transition zone thickness below hot spots and plume buoyancy flux.

1.21.2.2 Regional Transition Zone Structure

The global studies of the 410 and 660 discussed so far used mainly data from open global permanent networks and from other open permanent stations. Although the global coverage of broadband stations is continuously increasing, there are still large gaps, especially in the oceans. There are however many temporary or locally confined much denser deployments of seismic stations, not necessarily all broadband, which are used for detailed studies of the mantle transition zone. Such networks can answer questions that cannot be answered with sparse networks. Therefore, we also discuss detailed local or regional studies using temporary dense deployments of large numbers of

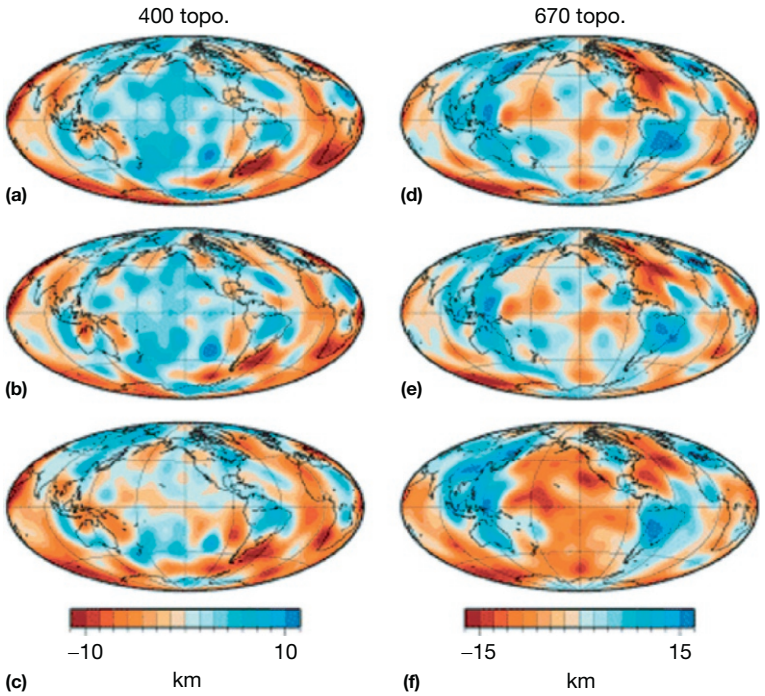

Figure 7 Topography of 410 and 660 (400 and 670 in PREM). 410 depth from SS precursors, (a) from Flanagan and Shearer (1998a) and (b) from Gu et al. (2003). (c) Results of joint inversion of SS precursors and mantle velocity. (d)–(f) Similar to (a)–(c), but for topography of the 660. Reproduced from Gu YJ, Dziewonski AM, and Ekstrom G (2003) Simultaneous inversion for mantle shear velocity and topography of transition zone discontinuities. *Geophysical Journal International* 154: 559–583, Figure 11.

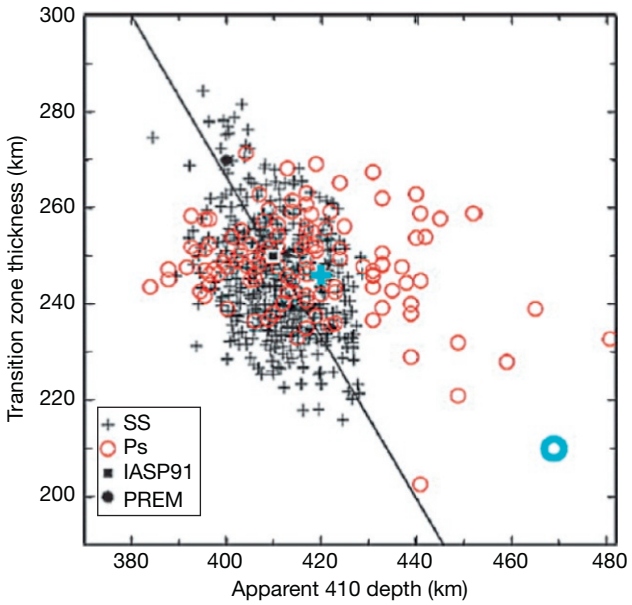

Figure 8 Thickness of mantle transition zone versus apparent 410 depths derived from arrival times of SS precursors and Ps conversions using the IASP91 global reference model. Ps depths (open circles) deeper than 430 km are all from ocean island stations. Straight line indicates relation between transition zone thickness and depth of 410 as expected from laboratory Clapeyron slopes. Thinner transition zone regions seem to concentrate in oceanic and thicker ones in tectonic areas. Reproduced from Li X, Kind R, Yuan X, et al. (2003b) Seismic observation of narrow plumes in the oceanic upper mantle. *Geophysical Research Letters* 30(6): 1334. http://dx.doi.org/10.1029/2002GL015411, Figure 2.

seismic stations in zones where variations of the transition zone thickness could provide results of interest. The lack of long recording time in these studies is overcome by the large number of closely spaced stations. In the following, we review results from such experiments in several regions of the world.

1.21.2.2.1 Japan

Japan is located in the Pacific Northwest subduction zone, below which the mantle transition zone is expected to be thick. First Ps studies found no depression of the 660 (Vinnik et al., 1996) or a strong depression beneath the GEOSCOPE station Inuyama in Japan (Thirot et al., 1998). Ps conversions from the Japanese broadband network have been used by Li et al. (2000a). They found the 660 at 700 km depth directly where the slab hits the transition zone but no larger-scale depression as it could be expected from the cold transition zone observed in a tomography study (Bijwaard et al., 1998). Kato et al. (2001) observed in ScS reverberations a weakly depressed 660. Again with receiver functions, Ramesh et al. (2005) observed anticorrelation of the 410 and 660 of the Philippine Sea plate below Japan. In near-vertical reflections from a regional earthquake recorded by 500 tiltmeters and 60 broadband seismometers in Japan, a 660 depressed by 15 km and an elevated 410 were found within the slab (Tono et al., 2005). Tonegawa et al. (2005) observed with Ps conversions the 660 depressed by 50 km and the 410 elevated by 30 km where it is hit by the slab. Also, Tonegawa et al. (2006) observed directly with data from 678 Hi-net tiltmeter stations the Pacific slab down to the elevated 410. The existence of a metastable olivine wedge below the 410 is demonstrated at the Japan slab by Kawakatsu and Yoshioka (2011) in P receiver functions (see **Figure 9**). Rare PP precursors from the 660 and a thickened transition zone have been identified below the Kurile slab by Schmerr and Thomas (2011). A thickened transition zone below Japan was also confirmed by an SS precursor study by Gu et al. (2012).

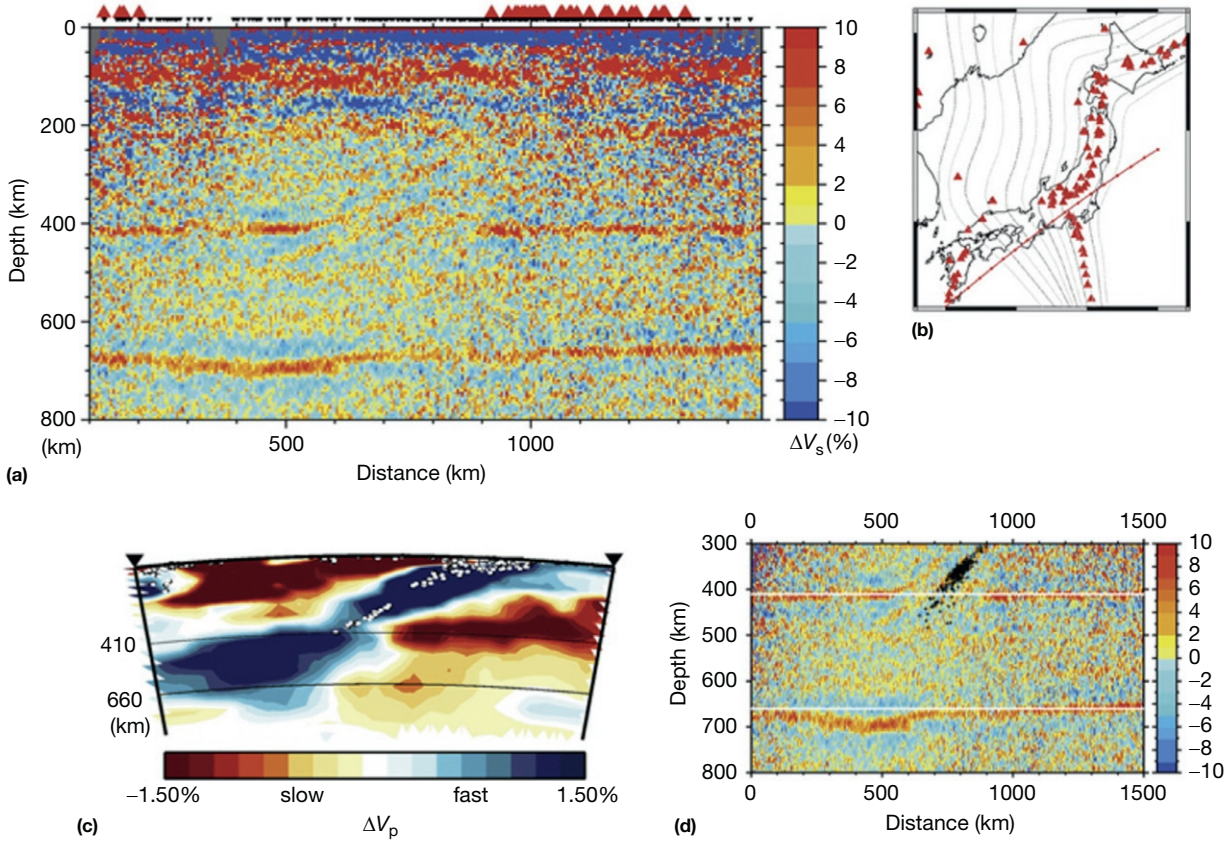

Figure 9 The reflectivity profile beneath southwest Japan. (a) Reflectivities given by receiver functions are measures of local S wave velocity jumps, as a P-to-S seismic wave conversion is sensitive to the S wave velocity change. Receiver functions are averaged over 3° wide range along the red line in (b). Red and blue colors correspond to velocity increase and decrease with depth, respectively. Red triangles and reversed black triangles plotted on the top, respectively, indicate active volcanoes and stations used for the imaging located within the cross-section range. The color scale is given in terms of an equivalent S wave velocity change at a first-order discontinuity in percent, but only relative values are meaningful. (b) A map of Japan with volcanoes (red triangles). Gray lines are isodepth contours (50–600 km) of the subducting Pacific slab. Distances in (a) and (d) are measured from the southwest end point (30° N, 130° E) of the red line, and dots on the red lines are given in a 100 km interval. (c) Image of a global seismic tomography along the same cross section (Obayashi et al., 2009). (d) Enlarged section of (a) with vertical exaggeration. Two white horizontal lines are drawn at depths of 410 and 660 km. Note the depression of 660 km discontinuity over about a 500 km width range. Plus marks indicate seismicity. Reproduced from Kawakatsu H and Yoshioka S (2011) Metastable olivine wedge and deep dry cold slab beneath southwest Japan. *Earth and Planetary Science Letters* 303: 1–10, Figure 1.

1.21.2.2.2 China

Ps conversions have been used by Niu and Kawakatsu (1996, 1998) and Yang and Zhou (2001) for studies of the 410 and 660 especially in northeast China, where the downgoing oceanic slab is reaching the mantle transition zone. Yuan et al. (1997) and Kind et al. (2002) found in southern Tibet good agreement of the depths of the 410 and 660 with the IASP91 global reference model. Li and Yuan (2003) found a 20 km thickened transition zone in northeast China where it is hit by the Pacific slab. A locally depressed 660 was also found by Ai and Zheng (2003) and Ai et al. (2003) in northeast China. Shen et al. (2008) and Chen and Ai (2009) have produced maps of the 410 and 660 from P receiver functions. Ai et al. (2008) found a small-scale thinning of the transition zone below the North Yellow Sea in receiver functions. Wang and Chen (2009) studied the velocity contrast at the 660 below the Kuriles and the Japan slab from wide-angle earthquake recordings. Zhang et al. (2010) found a depressed 410 under east Tibet at the border of the Sichuan Basin. Indications of a depressed 410 have also been found by Shen et al. (2011) at the northeastern margin of Tibet. Hu et al. (2013) found simultaneous depression of the 410 and 660 in eastern Tibet below the Longmenshan. Indications of a stagnant slab in the transition zone in eastern China have been reported by Gao et al. (2010) and Ye et al. (2011). Wang and Niu (2010) found in northeast China a thickened 660 transition using wide-angle array data. Tian et al. (2011) found the 410 and 660 across the Ordos Block and the Yinshan Mountains at their normal position. Yue et al. (2012) identified a 10–20 km topography variation of the 410 and 660 in central Tibet near the INDEPTH line.

1.21.2.2.3 Izu–Bonin and Tonga

Revenaugh and Jordan (1987), Roth and Wiens (1999), and Suetsugu et al. (2004) studied the 410 and 660 in the western Pacific with ScS reverberations. Thickening of the transition zone, deepening of the 660, and uplifting of the 410 have been shown by Richards and Wicks (1990), Vidale and Benz (1992), Wicks and Richards (1993), Collier and Helffrich (1997), Collier et al. (2001), and Castle and Creager (1997, 1998). Gilbert et al. (2001) confirmed such observations with ocean-bottom seismic data. Zhou et al. (2012) recognized a multiple 660 structure in S-to-P conversions below earthquake sources. Tibi and Wiens (2005) studied the 410 and 660 with local high-frequency seismic phases recorded by an array of broadband island stations. They found practically no change in the 410 depth; the 660 was depressed to 714 km (see **Figure 2**). Local seismic signals have also been used by Zang et al. (2006) to identify multiple discontinuities near the 660.

1.21.2.2.4 Andes

A thickened transition zone was observed beneath the Andean subduction in ScS reverberations by Clarke et al. (1995). Collier and Helffrich (2001) observed from near-source S-to-P conversions the 410 elevated by 60 km where it is hit by the slab and at normal depth in surrounding regions. Thickening of the transition zone from the Pacific to the Andean subduction was observed by Liu et al. (2003). Schmerr and Garnero (2007) studied the transition zone in the entire region of South America and surroundings using SS precursors. Wölbern et al. (2009) studied the transition zone below the southern Puna. Contenti et al. (2012) derived from SS precursors that a depressed 660 beneath the Andean slab is extending far to the east of the slab.

1.21.2.2.5 Yellowstone

Dueker and Sheehan (1997b) observed in receiver functions a 20–30 km thickness variation of the transition zone across the Yellowstone hotspot track. Beucler et al. (1999) found also in receiver functions no clear 410 beneath the Snake River Plain but a largely deflected 660. Similar observations have been made by Sheehan et al. (2000). Humphreys et al. (2000) found both discontinuities, the 410 and 660, uplifted in the Yellowstone hotspot track. Gilbert et al. (2003) and Fee and Dueker (2004) identified 20–40 km depth variation of both, the 410 and the 660, but uncorrelated with surface tectonics. Eagar et al. (2010) showed a thinned transition zone below Yellowstone in USArray data, which was later confirmed with the same data by Tauzin et al. (2013). Schmandt et al. (2012) found in USArray data the 660 deflected upward by 12–18 km beneath the hot spot and the 410 is within 5 km of its mean depth.

1.21.2.2.6 Hawaii

Li et al. (2000b) showed in receiver functions the thinning of the transition zone by 40–50 km in the southwest of the main island of the Hawaiian chain, which could indicate an inclined plume conduit.

A thinned transition zone was also found by Collins et al. (2002) below the Hawaiian swell in receiver functions and by Courtier et al. (2007) in ScS reverberations. A narrow transition zone was seen with SS precursors by Schmerr et al. (2010). Cao et al. (2011) observed also in SS precursors a large topography of the 410 and 660 west of Hawaii. Huckfeldt et al. (2013) found in receiver functions the deepening of the 410 from the northwest to the southeast below the Hawaiian chain and to the southwest of the Big Island.

1.21.2.2.7 Other hot spots

Below Iceland, Shen et al. (1996, 1998b, 2002) found with Ps conversions a 20 km thinned transition zone, whereas Du et al. (2006) did not observe an anomaly of the 660. Below the Eifel, Grunewald et al. (2001) and Budweg et al. (2006) showed a deepening of 410. Below the South Pacific superswell, Suetsugu et al. (2004) found a locally reduced transition zone thickness using ScS reverberations. Suetsugu et al. (2009), however, observed no transition zone thinning below most South Pacific hot spots. Leahy (2009) obtained a deepened and doubled 410 beneath Rarotonga, Cook Islands. Hooft et al. (2003) identified an 18 km reduced thickness of the transition zone below the Galápagos Islands. Shen et al. (1998a) observed at the Pacific Rise a normal transition zone thickness from an ocean-bottom experiment. Controversial results have been obtained at the Cape Verde. Helffrich et al. (2010) found a normal transition zone thickness, whereas Vinnik et al. (2012) obtained a thinned transition zone from receiver functions. No indication for any influence of a possible plume-like structure on the upper-mantle transition zone was shown in western Bohemia by Heuer et al. (2011) in P receiver functions.

1.21.2.2.8 North America

The 410 and 660 have been imaged by Bostock and Cassidy (1997) in receiver functions slightly earlier than predicted by IASP91 beneath the southern Slave craton. Dueker and Sheehan (1997a) found in the Colorado Rocky Mountains and High Plains a 20–40 km topography on the 410 and 660.

Gurrola and Bernard Minster (1998) observed a thinned transition at Pasadena. Li et al. (1998) mapped a depressed 660 in eastern North America. Gurrola and Bernard Minster (2000) and Ramesh et al. (2002) determined the transition zone thickness below a number of seismic stations in North America. Simmons and Gurrola (2000) found a multiple 660 in southern California. Gilbert et al. (2003) showed a 20–30 km uncorrelated topography of the 660 and 410 in the western United States. Ai et al. (2005) found in southern Alaska a thinned transition zone by 20–30 km with significant variations. A normal transition zone was observed by Wilson et al. (2005) in the southwestern United States along a Colorado Plateau–Rio Grande Rift–Great Plains seismic transect. Eagar et al. (2010) used in the Pacific Northwest a large number of P receiver functions recorded by the USArray for a transition zone study. They observed no 520, greater depth variations of the 410 than of the 660, and a thin transition zone beneath Snake River Plain. Cao and Levander (2010) found in the western United States an elevated 410 and a depressed 660 in the region of the subducted Gorda slab. Long et al. (2010) observed a normal transition zone thickness in the southeastern United States. Thompson et al. (2011) concluded that in the cratonic North America (Canada), the 410 and 660 are at their average global position, indicating no influence of the thick craton on the mantle transition zone.

1.21.2.2.9 Africa

Le Stunff et al. (1995) used P′P′ precursors recorded with the California array of broadband stations and detected a sharp and uplifted 660 below the East African Rift. Owens et al. (2000) found the transition zone beneath the East African Rift 30–40 km thinner than beneath the Tanzanian craton.

Nyblade et al. (2000) found no reduced transition zone thickness beneath Afar and concluded that the thermal anomaly does not reach the transition zone. Huerta et al. (2009) observed the 410 depressed locally beneath the Kenya rift, but the 660 depressed everywhere in Kenya and Tanzania. Gao et al. (2002) showed the 410 and 660 close to their normal position and concluded that there is no indication for a South African superplume in the transition zone and also no indication for other upper-mantle discontinuities. Stankiewicz et al. (2002) observed a normal transition zone in the Kimberley area and a slightly thickened transition zone beneath the Kaapvaal craton. Simon et al. (2003) found the 410 and 660 beneath Kaapvaal craton slightly deeper than normal. Blum and Shen (2004) observed a 20 km increased thickness of the transition zone in southern Africa. Wright et al. (2004) identified the 410 and 660 beneath the Kaapvaal craton slightly deeper than normal. Wang et al. (2009) studied the transition zone in Africa with the wide-angle technique. Cornwell et al. (2011) found in the Ethiopian Rift and Afar Region local thickness variations of the transition zone between 230 and 260 km. Reusch et al. (2011) observed the mantle transition zone thickness close to the global average beneath the Cameroon volcanic line, implying its upper-mantle origin.

1.21.2.2.10 Oceans

Gaherty et al. (1996) found along a Tonga–Hawaii corridor in ScS reverberations a thinned transition zone. Lee and Grand (1996) observed at the East Pacific Rise in SS precursors the 410 and 660 close to their normal depths. Kato and Jordan (1999) found in the western Philippine Sea in ScS reverberations a slightly thickened transition zone. Niu et al. (2000, 2002) identified at the South Pacific superswell the transition zone thinned by 15 km. Melbourne and Helmberger (2002) observed in wide-angle earthquake records no variation in the transition zone thickness below the East Pacific Rise over a 1000 km long profile orthogonal to the ridge. Li et al. (2003b) showed below ocean islands up to 15% thinning of the transition zone. In contrast, Tauzin et al. (2008) found no clear evidence for a thin transition zone beneath hot spots. Bagley and Revenaugh (2008) found in ScS reverberations a thinned transition zone in the Pacific upper mantle. Schmerr and Garnero (2006) used SS precursors for a study of the topography of the upper-mantle discontinuities in the central Pacific. Cao et al. (2010) observed the 410 and 660 at their expected position in the northern Pacific also in SS precursors. Silveira et al. (2010) observed in S receiver functions below the Azores the transition zone thickness is in agreement with the IASP91 global reference model.

1.21.2.2.11 Other regions

A normal transition zone thickness in agreement with the IASP91 global reference model was found in northern Eurasia by Mechie et al. (1993) in wide-angle nuclear explosion data, in southern Germany by Kind and Vinnik (1988), below India by Saul et al. (2000), at the Kola Peninsula by Dricker et al. (1996), in the North Sea by Helffrich et al. (2003), below the Arabian Shield by Benoit et al. (2003), below the eastern Alps by Kummerow and Kind (2004), in southern Ireland by Landes et al. (2006), and in central Tibet by Mechie et al. (2011). Only small changes in the depth of the 410 in subduction zones have been found by Flanagan and Shearer (1998b). A common delay of the arrivals from the 410 and 660 was obtained by Kumar et al. (2002) below the Arabian Shield and by Mohsen et al. (2005) below the Dead Sea region due to a relatively slow upper mantle. Alinaghi et al. (2003) found below the Baltic Shield the 410 and 660 signals arriving 2 s earlier due to a faster upper mantle. A thickened transition zone was found in East Antarctica by Reusch et al. (2008), in the eastern Himalaya and southern Tibet by Singh and Kumar (2009), in Central Asia by Tian et al. (2010), below the Alps by Lombardi et al. (2009) and Hetenyi et al. (2009), in northern India by Oreshin et al. (2011), below the Philippines by Ohtaki et al. (2002, in ScS reverberations), in the Mediterranean by Van der Meijde et al. (2005), and below the Venezuela–Caribbean plate boundary by Huang et al. (2010). A thinned transition zone was shown in the Kurile–Kamchatka subduction zone by Petersen et al. (1993a) and in southern California by Gurrola and Bernard Minster (1998). Relatively strong local variations of the transition zone thickness have been observed in Central Asia by Neves et al. (1996) in nuclear explosion data, in Indonesia by Saita et al. (2002), below the

Philippines by Wright (2009) with wide-angle data, below the Philippine Sea by Suetsugu et al. (2010), and at the Mariana slab by Tibi et al. (2006) with ocean-bottom seismometers.

1.21.2.3 Sharpness of 410 and 660

Benz and Vidale (1993) observed short-period precursors of P′P′ in the Indian Ocean from South American events, recorded by many short-period stations in California. They observed that both discontinuities (410 and 660) were <4 km sharp. Petersen et al. (1993b) found a sharper 410 (5–7 km) than 660 (20–30 km) from Ps conversions at several broadband stations in different regions.

Yamazaki and Hirahara (1994) used regional earthquakes recorded by the J-Array in Japan (S-to-P converted and reflected waves) and derived a discontinuity thickness of 5 km for both, the 410 and 660. Tonegawa et al. (2005) detected a sharp 660 and a variable 410 beneath Japan. Lebedev et al. (2002a) found a sharp 660 near the Japan slab from Ps data. Helffrich and Bina (1994) discussed the frequency dependence of the 410 signals. Van der Lee et al. (1994) discussed the influence of topography on the amplitudes of P-to-S converted waves. Priestley et al. (1994) found in nuclear explosion data in central Siberia a 35 km thick gradient at the 410 and a 4 km thick gradient at the 660. Ryberg et al. (1998) derived also from nuclear explosion data in northern Eurasia that the 660 is several kilometers wide and that the velocity jump across it is only half of the IASP91 value. They also argued that wide-angle data are not very sensitive to discontinuity gradients. Vidale et al. (1995) showed the 410 to be <10 km wide in the western United States from near-critical reflection records from nuclear explosions. Neele (1996) found that the velocity increase at the 410 occurs over a width of 4 km or less below the Gulf of California. Bostock (1996a) found also in Ps data a sharper 410 than 660 beneath the North American craton. Melbourne and Helmberger (1998) identified in wide-angle data a 14 km thick gradient zone at the 410 in the southwestern United States. Neves et al. (2001) found a 10 km sharp 410 and a 5 km sharp 660 beneath North America in wide-angle data. However, within the slab, a more complicated structure occurs. Xu et al. (1998) and Xu et al. (2003) found globally a sharp 660 (2 km or less) and a less sharp 410 from P′P′ precursors. Le Stunff et al. (1995) observed a sharp and uplifted 660 below the East African Rift in P′P′ precursors from a Fiji event recorded with the California array of broadband stations. Castle and Creager (2000) identified that the 660 is locally <10 km wide at the Izu–Bonin subduction zone using source side S-to-P conversions recorded in the western United States. Rost and Weber (2002) showed that the 410 is <6 km wide from array PP precursor studies in the Pacific Northwest. Tibi and Wiens (2005) concluded from short-period observations of local earthquakes a sharpness of 0–2 km for the 660 and 2–10 km for the 410 in the Tonga subduction zone. Estabrook and Kind (1996) concluded from the missing precursors of PP from the 660 that the velocity and density jump here is globally significantly smaller than predicted by the IASP91 global reference model (see **Figure 8**). This was confirmed by Shearer and Flanagan (1999) globally and by Ryberg et al. (1998) from summarizing wide-angle nuclear explosion data in northern Eurasia. Kato and Kawakatsu (2001) derived from SS precursors, Ps conversions, and ScS reverberations a locally larger S velocity and density jump at the 660 than at the 410 beneath the Pacific Northwest. This observation is in disagreement with the global observation of missing PP precursors by Estabrook and Kind (1996) and Shearer et al. (1999).

1.21.2.4 Low-Velocity Zone atop the 410

Song et al. (2004) observed in the northwestern United States a 20–90 km thick low-velocity zone above the 410 from wide-angle data, which they interpret as an indication of high water content in the transition zone (Bercovici and Karato, 2003; Youngs and Bercovici, 2009). Jasbinsek and Dueker (2007) found in the northern Rocky Mountains a low-velocity zone above the 410 using Ps conversions. Vinnik and Farra (2007) detected also such a zone below several globally distributed seismic stations. Bagley and Revenaugh (2008) and Bagley et al. (2009) studied the transition zone in the Pacific region using ScS reverberations and saw no low-velocity zone atop the 410, except at the Japan slab (50–75 km thick). Vinnik et al. (2009, 2010) identified in P and S receiver functions a low-velocity zone above the 410 in South Africa and in California. Schaeffer and Bostock (2010) found in P and S receiver functions below northern Canada a low-velocity zone at about 340 km depth. Tauzin et al. (2010) argued, based on P receiver functions, that a global low-velocity zone near 350 km depth exists, without any relation to the tectonic environment. Schmandt et al. (2011) found in P receiver functions a low-velocity zone at 25–60 km above the 410 in several regions in the western United States. Jasbinsek et al. (2010) found a low-velocity zone above the 410 at the Colorado Plateau and Rio Grande Rift. Chu et al. (2012) found also a low-velocity zone atop the 410 in the United States using wide-angle earthquake records.

1.21.2.5 The 520 Discontinuity

Shearer (1990, 1991, 1996) presented evidence in long-period SS precursors for the global existence of the 520 and determined the impedance contrast of the upper-mantle discontinuities. Bock (1994) discussed the influence of sidelobes on the observations of the 520 in SS precursors. Revenaugh and Jordan (1991a), Gaherty et al. (1996), and Kato and Jordan (1999) found the 520 in ScS reverberations along corridors in the Pacific. Cummins et al. (1992) observed no evidence for 520 north of Australia in short-period wide-angle earthquake recordings. Gossler and Kind (1996) confirmed the regional existence of the 520 in SS precursors. Mechie et al. (1993), Priestley et al. (1994), and Ryberg et al. (1996, 1997, 1998) found evidence for the 520 in northern Asia in nuclear explosion data. Deuss and Woodhouse (2001) observed the splitting of the 520 using SS precursors. Ai et al. (2005) observed the 520 in receiver functions in Alaska. Schäfer et al. (2009) detected the 520 in PP precursors.

1.21.2.6 Summary of the Upper-Mantle Transition Zone

The 410 and 660 are besides the Moho certainly the best-documented discontinuities in the upper mantle. In recent years, they have been observed with increased resolution in

SS, PP (only few 660 precursors), and P′P′ precursors, Ps and Sp conversions, and ScS-related phases. One clear result is that the P wave velocity jump across the 660 is globally a significant percentage below the values in present global reference models. This should influence the modeling of mantle convection. The global topography of the 660 seems to be larger than the topography of the 410. The question whether the 410 and 660 are globally anticorrelated, which, if true, would provide evidence in favor of the phase transition model in the olivine system, is much less clear. There are opposing observations. The thickness of the transition zone seems to vary globally by about 20–30 km (with the 410 and 660 not necessarily anticorrelated), indicating about a 200 K lateral temperature variation within the transition zone. There is widespread agreement that the seismic data support the idea that transformations in the olivine structure give rise to the 410 and 660 globally. The question of the correlation of the type of plates (oceanic or cratonic) and the transition zone thickness (or temperature) seems not clearly decided. Again, there are contradicting observations. Such a correlation between surface geology and transition zone structure would lead to serious problems with plate tectonics, since laterally moving lithospheric plates are not often considered to reach the mantle transition zone. Some tomographic models, however, seem to agree with this view. Ritsema et al. (2004) observed in tomographic data below the continental lithosphere down to 400 km depth a 1–1.5% higher velocity than below the oceanic lithosphere. Gung et al. (2003), however, interpreted high tomographic velocities in continental roots as being caused by anisotropy. The possibility of continental roots reaching several hundred kilometers deep and maybe even into the mantle transition zone was first suggested by Jordan (1975). Crucial for answering questions about the deep roots of continents would be the comparison with high-resolution data from undisturbed oceanic areas away from ocean islands, which are always anomalous. Such data can only be obtained from dense ocean-bottom seismic observations, which are very expensive. High-resolution data are so far only available for continents; therefore, a real quantitative comparison is not yet possible.

Most researchers agree that the 660 is depressed at subduction zones on a large scale. The amount of depression varies between 20 and 50 km. These results come from global observations and also from high-resolution local observations. Updoming of the 410 at subduction zones is much less certain. There are locally contradicting observations, although clear observations of updoming exist in Japan. The 410 seems in many cases poorly observed in subduction zones. A depression of the 410 due to metastable olivine in subduction zones is not yet observed clearly.

The transition zone structure beneath hot spots is less clear. There are fewer observations beneath hot spots because many are in oceanic regions. There are observations of thinning of the transition zone and also of a normal transition zone. The continued collection of high-resolution information on the 410 and 660 beneath hot spots should reliably answer the question of which plumes reach down to the transition zone and which do not.

Local studies with mobile networks or closely spaced long-term station deployments provide high-resolution information in some continental or oceanic regions. In general, most information from stable continents agrees with the global average values. This seems even true for regions like Tibet or the Alps. This leads to the conclusion that active lithospheric tectonics may not reach the transition zone (except for subduction zones and possibly plumes). Since the upper mantle is generally faster beneath continents than beneath oceans, both discontinuities frequently appear deeper under oceans than below continents. The continental values are closer than the oceanic values to those of the reference models (IASP91), which indicate that the reference models may be biased by consisting of a majority of continental data.

Only high-frequency data like P′P′ precursors or local reflections and conversions seem able to resolve sharpness (and other details like multiple discontinuities) of the 410 and 660. Relatively few of such observations are available and they confirm sharpness of just a few kilometers for both discontinuities. Teleseismic mantle phases (including Ps conversions) probably do not have sufficiently high frequencies to resolve the sharpness. If weak scattered waves (e.g., receiver functions) are used, the summation of many traces over a more or less large region is required. Such summation may lead to the contamination of discontinuity sharpness or impedance contrast by topography effects. Therefore, estimates of discontinuity sharpness with summation traces should be done with great care. Systematic high-frequency global studies of discontinuity sharpness and impedance contrast are still missing.

The discontinuity at 520 km depth is clearly observed in some regions but it is not clear in others. The 520 is thus not a laterally homogeneous global discontinuity, but it also cannot be considered a local one, because it has a relatively widespread distribution. Its existence does not seem to have any correlation with surface structures.

1.21.3 The Gutenberg Discontinuity (LAB)

The first seismic observations of a global low-velocity zone below the Moho (called the asthenospheric channel) were obtained by Gutenberg (1926, 1954, 1959) at 100 km depth from amplitudes and slownesses of P phases. Therefore, seismologists sometimes call this discontinuity the ‘Gutenberg’ discontinuity (often abbreviated as ‘G’ discontinuity). It is mainly reported in oceanic regions. The Lehmann discontinuity (Lehmann, 1961) is considered as the bottom of the asthenosphere (mostly observed in continental regions; Deuss and Woodhouse, 2002; Gu et al., 2001a). Since the Gutenberg discontinuity is a negative discontinuity (a reduction of velocity with depth), it is often identified with the LAB. Therefore, we will not always make a clear distinction between the terms ‘LAB’ and ‘Gutenberg discontinuity,’ although the terms are the result of entirely different definitions. The concept of a high-viscosity lithospheric layer overlying a low-viscosity asthenospheric layer was introduced to explain observations such as the postglacial uplift of Scandinavia (e.g., Barrell, 1914). Originally, the expressions ‘crust’ and ‘lithosphere’ were used synonymously (see a discussion by Gutenberg, 1959). Only after Mohorovicic (1910) had discovered a sudden increase of the seismic velocity at 50 km depth, which was later confirmed worldwide, was this discontinuity considered as the lower boundary of the crust (termed Moho).

Since then, the terms 'crust' and 'lithosphere' have gained different meanings. Later, with the rise of plate tectonics, the lithosphere–asthenosphere concept was expanded to explain large lateral displacements of continents by high-viscosity lithospheric plates floating over the low-viscosity asthenospheric upper mantle (see **Chapter 6.02**). Thermal and chemical definitions of the term 'lithosphere' have been introduced since then (Anderson, 1995). A somewhat different geodynamic concept was developed by Jordan (1975). The concept of Jordan (1975) comprises a tectosphere with continental roots that reach to 400 km depth and translate together with the continental lithosphere (Sipkin and Jordan, 1976, 1980).

The lithosphere is seismologically divided into two parts, the crust and the mantle, with the latter being the high-velocity mantle lid on top of the asthenosphere. Surface-wave observations of the high-velocity lid and the low-velocity asthenosphere have been obtained for many years (e.g., Dormann et al., 1960; Kanamori and Press, 1970; Knopoff, 1983). Direct seismic observations of the LAB remain a challenging task. A major problem is that the asthenosphere is a low-velocity zone. Thus, it is difficult to observe it with refracted and reflected seismic body waves. The Moho, in contrast, marks a sharp positive increase in velocity downward, which is easy to observe. Therefore, the Moho is well constrained on a global scale (Mooney et al., 1998; see **Chapter 1.11**). Fewer constraints on the depth of the LAB have been obtained from seismic body waves. A review of wide-angle results is given by Thybo (2006) (see **Figure 10**; see **Chapter 1.15**). Mostly surface-wave dispersion is used to measure the depth of the LAB. From these relatively low-resolution observations (compared to the high resolution of the Moho, which is obtained from short-period body waves), the LAB can only be imaged as a broad transition zone, and therefore, it is difficult to locate. The most important result of surface-wave studies is the larger thickness of the lithosphere beneath continents than below oceans (e.g., Gung et al., 2003). At present, the thickness of the lithosphere is considered to vary from a few kilometers at mid-ocean ridges to 200 km beneath stable cratons, with 80–100 km being the global average. The problems of detecting low-velocity zones with wide-angle seismic data are well known in the crust and are even greater in the mantle. Steep-angle body waves (similar to the seismic reflection method in crustal studies) are probably much more useful for detecting the Gutenberg discontinuity and mapping its topography. In recent times, the P receiver function technique has turned out to be very successful in imaging the crust–mantle boundary (e.g., Langston, 1979; Yuan et al., 2002). However, P receiver functions are less useful for detecting the Gutenberg discontinuity because crustal multiples sometimes arrive at about the same time as direct conversions from the Gutenberg discontinuity and therefore are hard to separate. The problem with crustal multiples can be solved if S-to-P conversions are applied instead. In this case, direct conversions are clearly separated from multiples. Direct conversions arrive in front of S, and multiples in the coda of S. S-to-P conversions have also long been used to study upper-mantle discontinuities (e.g., Bock, 1988, 1991; Jordan and Frazer, 1975; Sacks and Snoke, 1977; Sacks et al., 1979). They have been reintroduced in a modernized form as S receiver functions by Farra and Vinnik (2000) and Zhou et al. (2000). A more recent description of the technique is given by Yuan et al. (2006) and Kind et al. (2012). This still relatively rarely used technique is applied to S or SKS phases and adds a few more processing steps to the original Sp conversion technique. Such steps are, as in the P receiver function technique, source equalization by deconvolution and distance moveout correction. Both steps are applied in order to enable the summation of events from different distances and with different magnitudes and source-time functions. Thanks to the newly available large quantities of high-quality digital data, the conversion techniques enjoy increasing popularity. These techniques work very well, enabling especially observations of the LAB with a resolution

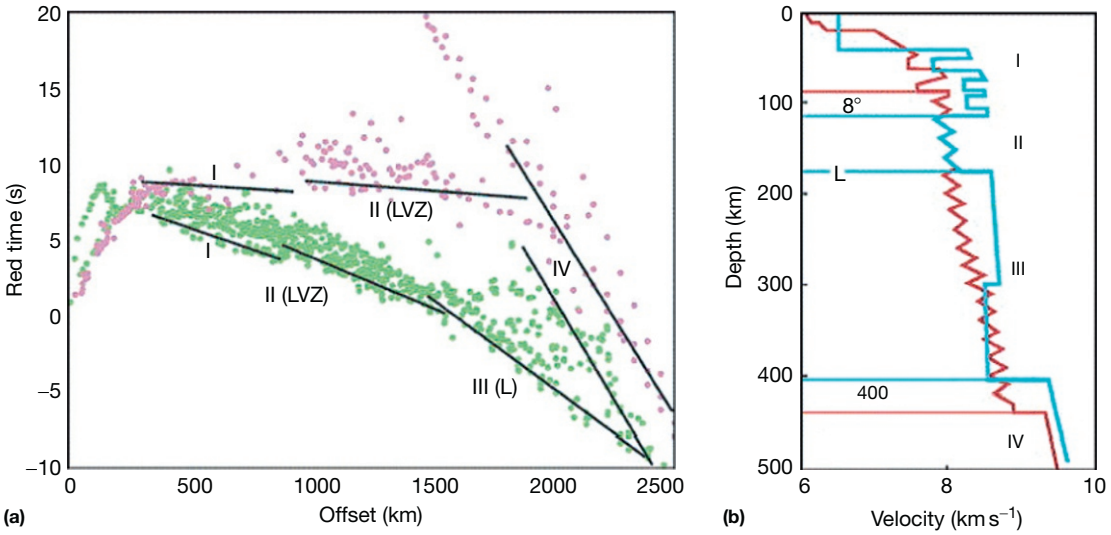

Figure 10 (a) Travel time–distance plot of collected long-range controlled source seismic data. Purple points are from tectonic active regions and green points from tectonic quiet regions, respectively. (b) Derived models for these areas (cold – blue, hot – red). The 8° discontinuity (or Gutenberg discontinuity, or LAB), the Lehmann discontinuity, and the 410 are shown. The asthenosphere is less pronounced in cold areas. Reproduced from Thybo H (2006) The heterogeneous upper mantle low velocity zone. *Tectonophysics* 416(1–2): 53–79, Figure 2.

so far only known for the Moho. In the following, we discuss briefly papers with possible observations of the LAB. A relatively early discussion about the global lithospheric thickness from seismic tomography, heat flow, and seismic anisotropy was published by Artemieva and Mooney (2001) and Artemieva et al. (2002). Also from anisotropy, Plomerova et al. (2002) obtained LAB depths between 200 and 250 km for the Precambrian shields and platforms, of about 100 km for the Phanerozoic continental regions, and 40–70 km beneath oceans.

1.21.3.1 Possible LAB Observations

1.21.3.1.1 Pacific

The LAB has been observed in long-period ScS reverberations in the Pacific area by Revenaugh and Jordan (1991b), Gaherty et al. (1996, 1999), Kato and Jordan (1999), and Bagley and Revenaugh (2008). Collins et al. (2002) detected the Gutenberg discontinuity at 80 km depth beneath the Hawaiian swell using ocean-bottom seismic stations. Li et al. (2004) found in S receiver functions the LAB beneath the Big Island at 100 km depth, where it is expected according to the age of the seafloor and to surface-wave observations. In addition, thinning of the LAB to 60 km along a narrow corridor below the island chain was also observed, which was interpreted as the rejuvenation of the lithosphere due to the passage of the Pacific plate over the Hawaiian hot spot. Wölbern et al. (2006) confirmed with P receiver functions these observations. Gung et al. (2003) studied the Lehmann discontinuity under continents and the Gutenberg discontinuity under oceans. Kawakatsu et al. (2009) identified the subducting Pacific lithosphere down to about 200 km depth (see **Figure 11**). Rychert and Shearer (2011) studied the oceanic lithosphere in the Pacific using SS precursors. They found agreement with the cooling model for an isotherm of 930 °C. Kumar et al. (2007) determined the LAB depth with S receiver functions at stations around the Indian Ocean and found evidence for a thin Indian lithosphere. Kumar et al. (2011a) used P and S receiver functions from borehole seismometers below the Philippine Sea, away from islands. They found the LAB near 76 km. Kumar and Kawakatsu (2011) and Kumar et al. (2011b) imaged the LAB along continental margins with S receiver functions using coastal stations (also across the San Andreas Fault). They found a correlation of the LAB depth with the age of the oceanic plate. Schmerr (2012) observed in SS precursors LAB variations in the entire Pacific basin between 40 and 75 km depth. Rychert et al. (2012) studied the oceanic lithosphere using body-wave and surface-wave techniques.

1.21.3.1.2 China and Tibet

Oreshin et al. (2002) and Vinnik et al. (2004) did the first S receiver function studies in Central Asia and found in the Tian Shan region the LAB at shallow depths (near 90 km). Kumar et al. (2005a, 2006) mapped the LAB in the region of the Tian Shan and western and central Tibet. As a very noticeable result, Zhang et al. (2010) observed the LAB below eastern Tibet at a shallower depth than beneath the cratonic Sichuan

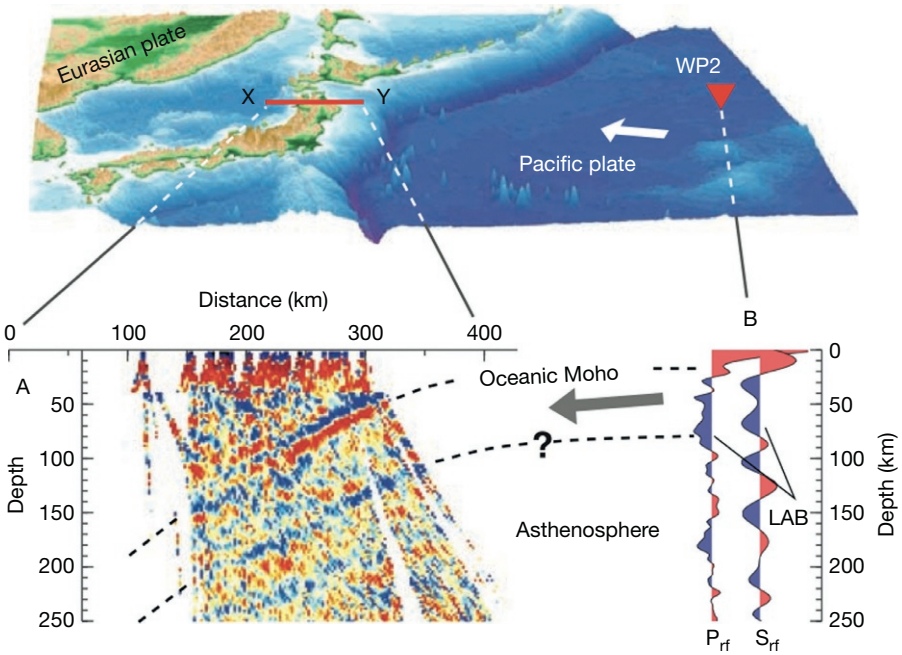

Figure 11 Receiver functions of the subducting Pacific plate beneath northeast Japan. In the topographic map, the inverted red triangle indicates the location of seismic station WP2, which is deployed at a depth of 460 m below the seafloor with a water column of 5566 m thick. (a) P receiver function image along the profile XY using dense land seismic data of Hi-net from Japan. Red and blue colors indicate velocity increase and decrease (from shallow to deep), respectively. The top surface of the slab and the oceanic Moho are clearly imaged, as well as the bottom surface of the slab (i.e., subducting LAB). (b) P and S receiver functions for WP2. Negative phases associated with a shear wave velocity drop marked as LAB appear to correspond to the strong negative (blue) signature of the subducting slab below Japan. Reproduced from Kawakatsu H, Kumar P, Takei Y, et al. (2009) Seismic evidence for sharp lithosphere–asthenosphere boundaries of oceanic plates. *Science* 324: 499–502. http://dx.doi.org/10.1126/science.1169499, Figure 2.

Basin. Hu et al. (2011) and Zhang et al. (2012) made similar observations in eastern Tibet and in parts of northern–eastern Tibet. Sodoudi et al. (2006a) found the LAB also in S receiver functions at 70 km below the Yangtze craton and at 60 km below the North China platform. Chen (2009, 2010) and Chen et al. (2008) found beneath the North China Craton a correlation between lithospheric structure and structure of the mantle transition zone. Kind and Yuan (2010), Zhao et al. (2010), and Zhao et al. (2011) imaged with S receiver functions the stacking of the Tibetan LAB above the subducting Indian LAB. Continental subduction of India below Tibet was modeled by Chemenda et al. (2000). Xu et al. (2011) obtained from S receiver functions of the Hi-CLIMB (Himalayan–Tibetan Continental Lithosphere during Mountain Building) experiment the LAB at 80 km depth below the Himalayas and at 130 km depth below central Tibet. Devi et al. (2011) and Mandal (2012) identified the LAB in northeast India at 90–135 km, below the Himalayas near 180 km and below the Deccan volcanic province near 70 km, respectively.

1.21.3.1.3 Africa

Qiu et al. (1996) and Priestley (1999) derived from P receiver functions, wide- and steep-angle seismic data, Pn and Sn data, and surface-wave data a lithospheric thickness of 120–160 km in southern Africa. Priestley and McKenzie (2002) found the LAB beneath southern Africa at 176 km depth from regional seismic data. Vinnik et al. (1996), Wittlinger and Farra (2007), and Kumar et al. (2007) found the LAB at about 300 km. Savage and Silver (2008) found a negative discontinuity at about 150 km, similar to Hansen et al. (2009a,b) and Vinnik et al. (2009). Fishwick (2010) compared tomographic and receiver function LAB observations in South Africa. Wölbern et al. (2012) found in S receiver functions a velocity drop of 6–9% below the Tanzanian craton at 50–100 km depth and another velocity drop of 12–24% at a depth of 140–200 km. Sodoudi et al. (2013) observed layering of the mantle lithosphere underneath South Africa and picked the negative interface at ~280 km as the LAB.

They interpreted another negative discontinuity at 150 km as midlithospheric discontinuity (MLD) caused by compositional changes.

1.21.3.1.4 Europe and the Middle East

A low-velocity zone in the cratonic upper mantle near 100 km depth has frequently been observed in controlled source (including nuclear explosions) seismic data (Nielsen et al., 1999; Thybo, 2006; Thybo and Perchuc, 1997). The Svekalapko Seismic Tomography Working Group (2004) found the LAB at 100–130 km depth below Finland in wide-angle data. Olsson et al. (2007) applied the S receiver function technique to data of the Swedish National Seismic Network and found a layered structure of the upper mantle with the LAB near 200 km. Geissler et al. (2010) studied the LAB at permanent seismic stations in Central Europe with S receiver functions. Sodoudi et al. (2006b) studied the collision of the African and European lithospheres in the Hellenic arc and found the African lithosphere flattening under the northern Aegean at 250 km depth. Angus et al. (2006) found in S receiver functions the LAB in eastern Turkey at 60–80 km depth and below the Arabian Shield at 100–125 km depth. Mohsen et al. (2006) determined the LAB depth around the Dead Sea transform fault with S receiver functions. Hansen et al. (2007) found also in S receiver functions a thin lithosphere below the Red Sea and thickening toward the interior of the Arabian Peninsula. Sodoudi et al. (2009) found in S receiver functions the LAB beneath the Alborz Mountains in Iran at 90 km depth, similar to Taghizadeh-Farahmand et al. (2010), who found the LAB in the northwest of Iran near 85 km depth. Dündar et al. (2011) mapped the LAB in the region of southern Spain, the Alboran Sea, and northern Morocco using S receiver functions. Kumar et al. (2005b) observed the LAB beneath Iceland and Greenland using S receiver functions from several temporary seismic broadband projects and found the LAB at a nearly constant depth of 80 km beneath Iceland (confirming earlier results of Vinnik et al., 2005b) and thickening from 80 to 120 km from east to west beneath Greenland. Kind et al. (2013) proposed a mechanism to create the thick cratonic lithosphere based on the observation of lithospheric stacking beneath Scandinavia by S receiver functions.

1.21.3.1.5 North America

Parker et al. (1984) derived from P residuals the upwarping of the asthenosphere below the Rio Grande Rift. Bostock (1999) extended structures in the uppermost mantle obtained from controlled source experiments into larger depths using receiver functions and concluded that the cratons might be stabilized by shallow subduction. Rychert et al. (2005, 2007) found a sharp LAB in P receiver functions that were clearly separated from crustal multiples (see **Figure 12**). They found in eastern North America the LAB at 90–110 km depth with a velocity decrease of 3–11% over a depth range of 11 km or less and concluded that a few percent of partial melt or enrichment of volatiles in the asthenosphere could cause such a sharp LAB. Li et al. (2007) found the LAB in the western United States at depths < 100 km with S receiver functions. Moorkamp et al. (2007) jointly interpreted receiver functions and magnetotelluric data in a search for the LAB in the Slave craton, Canada. Miller and Eaton (2010) studied a S receiver function profile from west to east through Canada and found a shallow LAB (about 85 km) in the west and a deeper one (about 260 km) in the cratonic part. They also found in the cratonic part a shallower MLD. Lekic et al. (2011) produced a LAB map in southern California from receiver functions. Levander and Miller (2012) studied S receiver functions in USArray data and observed the LAB in the western United States at about 50–70 km depth and below Yellow Knife and the Colorado Plateau near 150 km, respectively. Kumar et al. (2012a) and Kumar et al. (2012b) imaged with S receiver function data of the USArray project the LAB in the United States. They found a shallow negative discontinuity in the entire United States (near 100 km depth), which is in agreement with earlier LAB determinations only in the western part of the United States, not in the cratonic eastern part. No clear indication of a deeper LAB was found in the cratonic United States (see **Figure 14**).

1.21.3.1.6 South America

Heit et al. (2007) imaged the LAB depth in South America, including the subducting slab, with data from permanent stations. Sodoudi et al. (2011) observed the subducting Nazca

LAB beneath northern Chile in P and S receiver functions and estimated the thickness of the subducting Nazca lithosphere.

1.21.3.1.7 General observations

Eaton et al. (2009) discussed geophysical and geochemical causes of the LAB in cratons and compared it with observations. Romanowicz (2009) discussed shallow low-velocity zones below cratons (near 100 km). Rychert and Shearer (2009) studied the global LAB structure with P receiver functions. They found a global negative discontinuity that they interpret as LAB in most regions, except below cratons, where it might be a new MLD. Jones et al. (2010) compared LAB depth determinations with seismic and electromagnetic data. Kumar et al. (2010) skipped the deconvolution in the receiver function technique and used plain summation of many traces without deconvolution. They also showed that the LAB can be observed by the P wave reverberation within the lithosphere. Pasyanos (2010) compared different methods for determining the LAB depth. Bartzsch et al. (2011) discussed possibilities to detect the LAB with surface-wave data.

Rychert et al. (2010) discussed the disagreements of new receiver function results with previous ideas about the structure of the lithosphere below cratons. Fischer et al. (2010) reviewed globally receiver function observations of the LAB and MLD. Abt et al. (2010) observed in S receiver functions a negative discontinuity (downward velocity decrease) in the United States between about 50 and 100 km depth, which was interpreted in the western part as LAB and in the cratonic part as MLD. No deep LAB was found in the receiver functions in the cratonic United States.

Yuan and Romanowicz (2010) interpreted a downward velocity decrease beneath cratonic North America near 100 km depth seen in receiver functions as the MLD rather than LAB (see **Figure 13**). Angus and Thomson (2012)

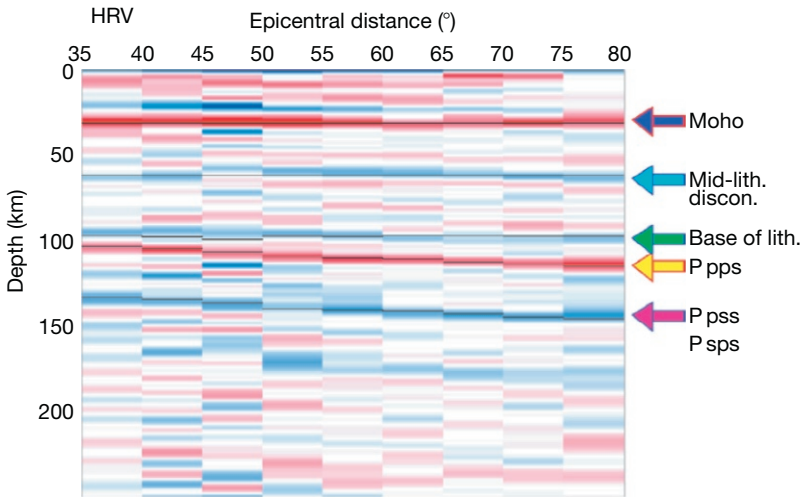

Figure 12 Stacks of P receiver functions at the Harvard station as function of epicentral distance. A number of conversions from upper-mantle discontinuities and crustal multiples are visible. Especially important is the observation of the base of the lithosphere, which is clearly separated from crustal multiples and indicates a sharp LAB (11 km or less). Reproduced from Rychert CA, Fischer KM, and Rondenay S (2005) A sharp lithosphere–asthenosphere boundary imaged beneath eastern North America. *Nature* 436: 542–545, Figure 1 of supplementary information.

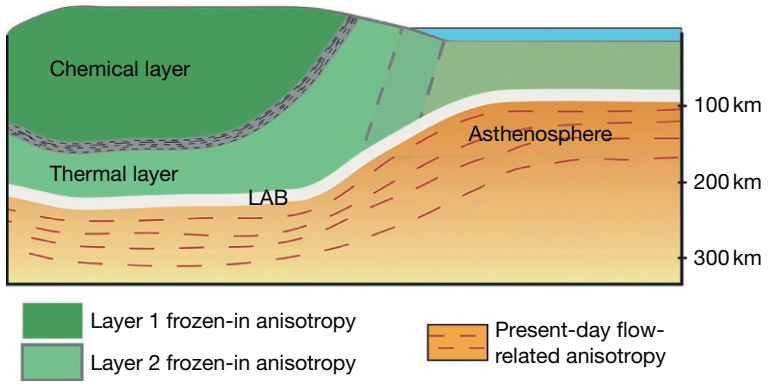

Figure 13 Cartoon illustrating the inferred stratification of the lithosphere. Beneath the craton, three layers of anisotropy are present: two in the lithosphere (layers 1 and 2) and one in the asthenosphere. Layer 1 corresponds to the chemically distinct, depleted Archean lithosphere, and layer 2 is the thermal root, separated from the asthenosphere by the LAB, which is at relatively constant depth beneath the stable part of the continent but rapidly shallows between the tectonic part of the continent (in the western United States) and in the oceans. The boundary between layers 1 and 2 is seismically sharp but its fine-scale structure is likely to be complex. The depth extent of the zone of present-day flow-related anisotropy is not tightly constrained by our study. Reproduced from Yuan H and Romanowicz B (2010) Lithospheric layering in the North American craton. *Nature* 466: 1063–1069. http://dx.doi.org/10.1038/nature09332, Figure 5.

computed theoretical conversions at an anisotropic LAB. Kind et al. (2012) reviewed the receiver function technique and its application for the search of the LAB (see **Figure 14**). Ford et al. (2010) studied receiver functions in Australia. They found the LAB in the Phanerozoic parts near 100 km depth in agreement with surface-wave data. Similarly, a shallow negative discontinuity was also found in cratonic parts of Australia and interpreted as MLD. At the depth of the expected LAB, no receiver function signals were found. Sodoudi et al. (2013) concluded that sharp boundaries generated by frozen-in anisotropy and compositional changes can result in an irregularly stratified structure, which can be identified in S receiver functions.

1.21.3.1.8 Summary of the Gutenberg discontinuity (LAB)

There are many body-wave observations confirming the existence of a low-velocity zone beneath the Moho. The S receiver function method seems to be especially successful in detecting and mapping the LAB. Practically in all regions where this technique was used to search for the LAB, it was indeed found. From this, it follows that the LAB is very likely a much clearer discontinuity than was previously thought. The missing observations at shorter periods than surface-wave periods were probably only due to the lack of an appropriate technique. So far, not many studies have been carried out to measure the sharpness or the size of the velocity jump of the LAB in different regions. The amplitude of the LAB conversion seems, in many cases, to be close to half that of the Moho signal, which would indicate an accordingly smaller step in velocity. The question if the shallow low-velocity zone beneath cratons, which gained recently much attention, has a so far unknown petrophysical explanation within the lithosphere or if cratons are a result of a 'lithospheric stacking' process (see, e.g., Pearson, 1999 or Griffin et al., 2003) seems still open. A contemporary example of lithospheric stacking might be the case of Tibet where a craton is now being formed (McKenzie and Priestley, 2008). So far, the proposed deep

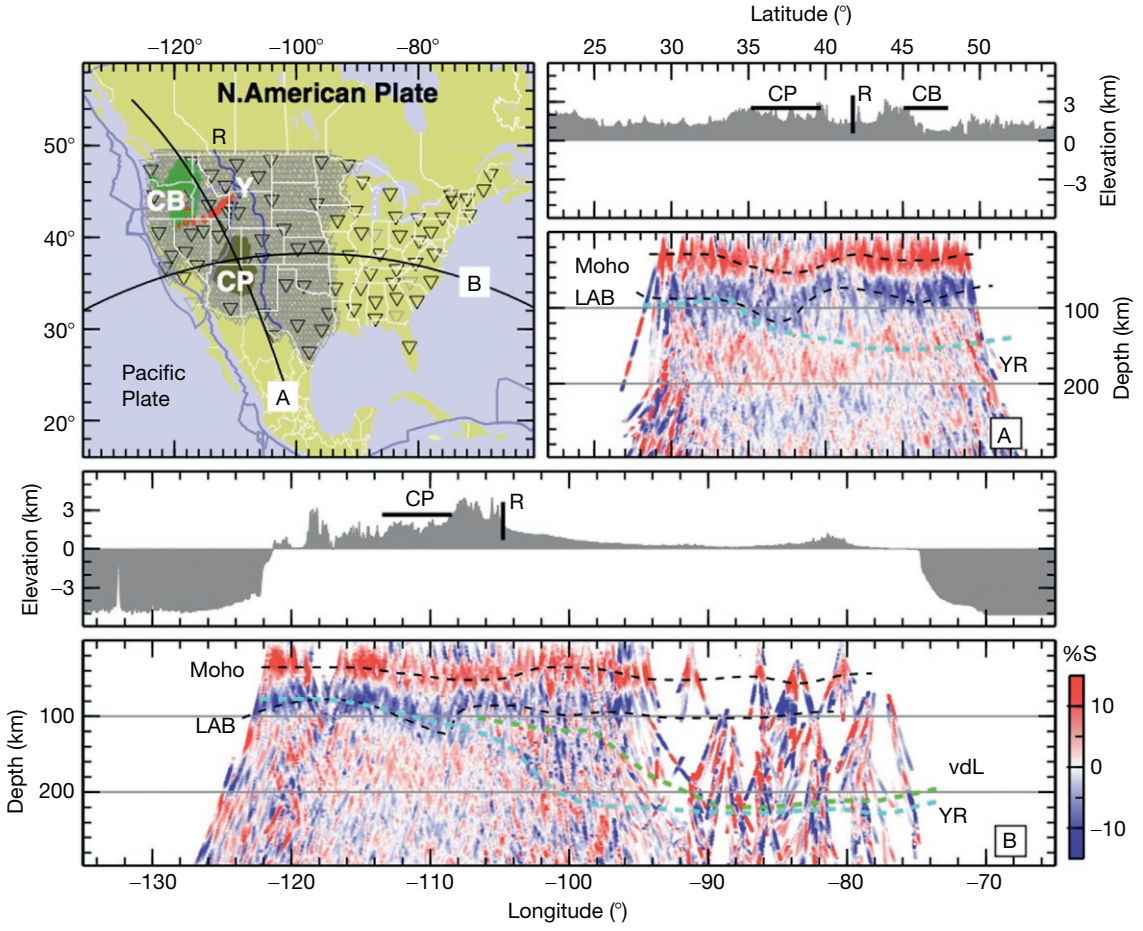

Figure 14 Migrated S receiver function images along two profiles A and B in the United States (locations are marked in the map shown above). CP is the Colorado Plateau, CB is the Columbia River Basalt, and R is the boundary of the Rocky Mountains. Data of the USArray (http://www.usarray.org/) are used west of 94° W and data from the permanent US network east of 94° W. The black inverted triangles are the permanent seismic stations used and the gray inverted triangles are the USArray stations. Two main discontinuities are observed, the Moho and a single negative discontinuity beneath the Moho around 100 km depth (about 140 km below the Colorado Plateau), which is suggested to be the LAB. This interpretation agrees in the western United States and at the east coast with LAB observations from surface waves. In the central cratonic part of the United States, this signal is interpreted as midlithospheric discontinuity by Abt et al. (2010). The dashed lines (labeled YR and vdL) mark the thickness of the lithosphere obtained from surface-wave data by Yuan and Romanowicz (2010) and Van der Lee (2001), respectively. Reproduced from Kind R, Yuan X, and Kumar P (2012) Seismic receiver functions and the lithosphere–asthenosphere boundary. *Tectonophysics* 536–537: 25–43, http://dx.doi.org/10.1016/j.tecto.2012.03.005, Figure 20.

continental roots (Jordan, 1975) have apparently rarely been observed as seismic discontinuities. There are, however, many tomographic indications of such deep roots (e.g., Masters et al., 1996; Ritsema et al., 2004; Su et al., 1994). The rapidly increasing number and quality of upper-mantle studies with high-resolution scattered body-wave studies may lead to a significant expansion of our knowledge of the deep structure of cratons and lithospheric dynamics (see **Section 1.21.2.1**).

1.21.4 The Lehmann Discontinuity

The Lehmann discontinuity (Lehmann, 1961, 1964) is defined to be a positive (velocity increase downward) seismic discontinuity at about 220 km depth. It is thought to represent the bottom of the asthenosphere, or alternatively the lower boundary of the continental roots (Anderson, 1979). It is a significant discontinuity in the PREM global reference model (Dziewonski and Anderson, 1981), but does not appear in the IASP91 global reference model (Kennett and Engdahl, 1991). Although local earthquake records allowed the original detection of the Lehmann discontinuity (usually employing wide-angle seismic data), most confirmations of this discontinuity come from other types of seismic data. These are SS precursors, ScS reverberations, receiver functions, or other types of scattered teleseismic waves. In the following, we list a number of observations of structures, which could be related to the Lehmann discontinuity.

Shearer (1990) found in long-period SS precursors no evidence for the global existence of a discontinuity near 220 km depth. Vidale and Benz (1992) found at 210 km depth the bottom of the asthenosphere near subducting slabs. Priestley et al. (1994) found the bottom of a low-velocity zone in central Siberia from nuclear explosions at 210 km depth. Gu et al. (2001a) used also SS precursors and found a variable Lehmann discontinuity preferably under continents and less under oceans (**Figure 15**). Deuss and Woodhouse (2002) have observed the Lehmann discontinuity globally under oceans and continents also using SS precursors. Deuss and Woodhouse (2004) have also inferred globally a negative Clapeyron slope for the Lehmann discontinuity from depth variations and tomographic upper-mantle velocities.

It is also suggested that the Lehmann discontinuity may be the lower boundary of an anisotropic asthenosphere. Karato (1992) proposed that the Lehmann discontinuity might be caused by a change of the preferred orientation of olivine crystals as consequence of a change of the deformation type. Gaherty and Jordan (1995) described the Lehmann discontinuity as transition from anisotropic lithosphere to more isotropic lower tectosphere beneath continents using ScS data. Gaherty et al. (1996) and Kato and Jordan (1999) found the Lehmann discontinuity at 166 km depth below an anisotropic asthenosphere in the Tonga–Hawaii corridor and in the western Philippine Sea, also from ScS data. Gung et al. (2003) suggested that the Lehmann discontinuity under continents and the Gutenberg discontinuity under oceans might both be associated with the bottom of the lithosphere. Gu et al. (2005) reported seismic anisotropy beneath the East Pacific Rise reaching down to 260 km, where a discontinuity was found. They used surface waves and travel times of body waves. Vinnik et al.

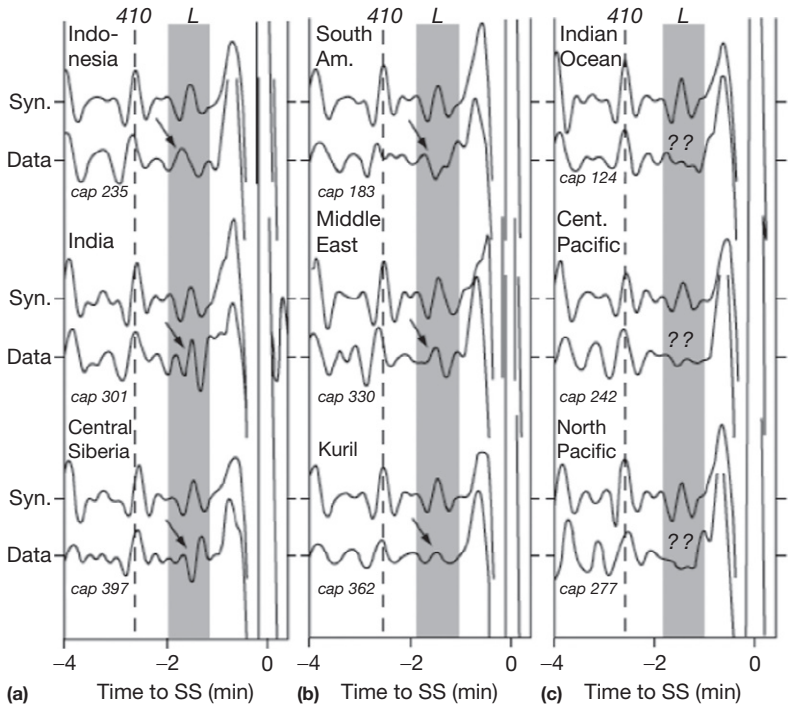

Figure 15 (a) Three S220S precursor stacks showing clear arrivals from the Lehmann discontinuity (thick lines – data, thin lines – synthetics from the PREM). (b) Three stacks in regions with marginal observations of the Lehmann discontinuity. (c) Three stacks in regions with no detectable Lehmann discontinuity. Reproduced from Gu Y, Dziewonski AM, and Ekstrom G (2001a) Preferential detection of the Lehmann discontinuity beneath continents. *Geophysical Research Letters* 28: 4655–4658, Figure 2.

(2005a), however, found in Sp conversions a discontinuity at 200 km depth in the northwest of the United States and concluded that anisotropy is not present at this depth.

There are also P receiver function reports of observations of the Lehmann discontinuity. Bostock (1996b) found evidence for a weak 220 km discontinuity beneath the Canadian part of the North American craton in P receiver functions. Bostock (1998) observed a west–east dipping structure between 170 and 230 km depth below Yellow Knife. Li et al. (2002) found from Ps data a discontinuity at 270–280 km depth beneath eastern North America.

There are also a number of wide-angle observations and other data that could be attributed to the Lehmann discontinuity. Drummond et al. (1982) and Hales (1991) found indications for a discontinuity near 200 km depth from wide-angle data in Australia and North America. Kaila et al. (1999) observed from wide-angle studies indications of the Lehmann discontinuity beneath large regions of the Andes. Rost and Weber (2001) found a discontinuity at 200 km depth in the northwest Pacific using PP precursors. Abramovitz et al. (2002) found in wide-angle data from Scandinavia a discontinuity at 150 km depth, which they considered as the base of the low-velocity zone. Wittlinger et al. (2004) interpreted from S receiver function data the bottom of the low-velocity zone at 120–180 km depth below Tibet. In summary, there are many reports indicating a widespread Lehmann discontinuity. There are several works obtained with the same technique (SS precursors), which have led to a first more or less global view. Also, anisotropy seems to play a significant role in the explanation of this discontinuity. There are confirmations from various other techniques, but SS precursors seem to be the most promising technique for obtaining a comprehensive global image of the Lehmann discontinuity. One problem of this technique is, however, its relatively low resolution due to the long periods of the SS precursors.

1.21.5 The Hales Discontinuity

Green and Hales (1968), Hales (1969, 1972), and Hales et al. (1980) reported positive (velocity increase downward) seismic discontinuities at 60–90 km depth below the United States and other regions from long-range controlled source experiments. Since then, seismic discontinuities found in this depth range have frequently been called the 'Hales discontinuity,' 'H,' or '80 km discontinuity.' These expressions stand for discontinuities within the lithospheric mantle lid. There have been many active and passive experiments from which such discontinuities have been reported.

Zandt and Randall (1985) observed in shear-coupled Pl modes a discontinuity between 70 and 80 km depth under North America, which they attributed to the Hales discontinuity. Revenaugh and Jordan (1991b) reported a mean depth of the Hales discontinuity of 65 km beneath the southwestern Pacific from ScS reverberations. Sandvol et al. (1998) found a discontinuity at 80–100 km depth below the Arabian Shield in receiver functions.

The Hales discontinuity has frequently been related to anisotropy. Fuchs (1983) described anisotropic discontinuities in the lower lithosphere below southern Germany. Zhang and Lay (1993) found a depth of 80–90 km for the Hales discontinuity beneath the western Pacific region from sSH precursors. Bostock (1997, 1998) observed an anisotropic layer at 70–80 km depth below the Slave craton in Canada. Levin and Park (2000) found an anisotropic layer at 70 km depth below the Arabian Shield, which they attributed to the Hales discontinuity. Saul et al. (2000) reported an anisotropic discontinuity at 90 km depth below the Indian Shield.

Discontinuities in the mantle lithosphere have been known for a long time from controlled source long-range profiles (e.g., Hirn et al., 1973; Kind, 1974; see **Chapters 1.08** and **1.15**). Egorkin et al. (1987) reported from records of 'peaceful nuclear explosions' discontinuities in the depth range between 80 and 100 km beneath northern Russia. Pavlenkova (1996) reviewed global controlled source profiles and concluded that, among other local discontinuities in the lower lithosphere, a global discontinuity exists at 80–100 km depth with velocities below the discontinuity of 8.4–8.5 km s^{-1}. Hajnal et al. (1997) found a discontinuity at 75 km depth under central North America. Also, in seismic reflection data, signals are observed from the depth range of the Hales discontinuity. For example, Steer et al. (1998) concluded from such data that a global discontinuity at 80–100 km depth may exist. Musacchio et al. (2004) reported an anisotropic layer beneath the Canadian Shield in the mantle lid from LITHOPROBE experiments.

A very characteristic feature of long-range controlled source seismic profiles is the teleseismic propagation of high-frequency Pn waves. This phenomenon has been reviewed recently by Fuchs et al. (2002) and interpreted as being caused by randomly distributed scatterers in the mantle lid with high aspect ratio and dimensions in the 10 km range. Tittgemeyer et al. (1996) modeled teleseismic Pn assuming a 1D model for the mantle lid with random velocity fluctuations. An alternative interpretation was given by Nielsen and Thybo (2003), who interpreted this observation as a whispering gallery effect. In conclusion, there are many reports from different places around the globe about a discontinuity that could correspond to the Hales discontinuity. Most of these reports come from wide-angle controlled source studies. There are, however, also a number of reports from steep-angle reflection experiments. Reports from P receiver function studies are rarer, probably since crustal multiples mask such deep phases. Receiver functions, however, seem frequently to have energy from this depth range on the transverse component, which is very likely indicative for anisotropic discontinuities in this depth range. Discontinuities certainly exist in the mantle lithosphere. However, it has not yet been shown that a single Hales discontinuity is a global feature. Many local discontinuities are seen in various parts of the mantle lithosphere. In addition, a global distribution of small-scale scatterers is probably responsible for long-range propagation of high-frequency Pn waves. There are still much too few homogeneous data available for reliable global analysis of the Hales discontinuity.

1.21.6 Conclusions

Historically, when seismologists started to study the Earth's interior, they were looking for globally existing discontinuities, since they explained the clearest seismic observations well.

Consequently, the core–mantle boundary, the crust–mantle boundary, and the boundary between the inner and outer core were discovered. These discontinuities have, since then, been confirmed as global boundaries and many of their details are now known and more details are still being discovered. Gutenberg suggested another discontinuity in the uppermost mantle, also in the early days of seismology. This discontinuity was later frequently associated with the LAB, following the development of plate tectonics. However, the global distribution of the Gutenberg discontinuity is still much less well known. One reason for this is certainly that the Gutenberg discontinuity is the upper boundary of a low-velocity zone, which is difficult to detect with classical seismic techniques. In the second half of the twentieth century, two more global seismic discontinuities were suggested, the Lehmann discontinuity as the bottom of the asthenosphere and the Hales discontinuity within the mantle lithosphere. Both of these discontinuities are still not reliably confirmed as global discontinuities. There are less systematic reports about observations of additional discontinuities, which are not treated here. The best-known global upper-mantle discontinuities are the ones located at average depths of 410 and 660 km. They are mostly explained by phase changes in the olivine system, in agreement with high-pressure laboratory experiments. Oceanic upper-mantle data seem to be crucial for the final confirmation. Downbending of the 660 discontinuity at subduction zones is confirmed by many reports. Globally, the 660 seems to be more a discontinuity of the shear modulus then of the bulk modulus.

The data used for the detection of seismic discontinuities in the Earth's interior are historically just travel times of seismic phases. These travel times have been obtained from sparsely distributed seismic stations. Since the advent of digital seismic waveform data, many more details have been learned about the Earth's structure in general and discontinuities in particular. New techniques have been developed. The most important ones use waves scattered at discontinuities (conversions, precursors, and multiples). These methods depend heavily on data summation techniques, since scattered phases are small in amplitude and must be enhanced by a combination of many records. Present initiatives toward increased efforts to significantly increase the collection of seismic data (e.g., USArray) not only will therefore lead to more details about structures already known to exist but also will likely discover additional structural elements unknown so far. The expected new data together with new techniques may lead to another revolution in our knowledge about the dynamics of the solid Earth, which is a fundamental part of our environment.

Acknowledgment

We wish to thank Xiaohui Yuan, Forough Sodoudi, and Jeff Gu for reviewing the manuscript and for their useful suggestions.

Glossary

Attenuation Loss of signal amplitude during propagation. Intrinsic attenuation involves irreversible anelastic losses; scattering attenuation involves partitioning of energy into separate waves.

CMB The core–mantle boundary is the surface defined by the contrast in composition between mantle rocks and core molten alloy. A huge density contrast and change in physical properties make this a sharp boundary, with very limited mass flux across it at present.

D″ Designation for the lowermost 200–300 km of the lower mantle. This region is distinct from the overlying mantle in that the seismic velocity variations are not consistent with homogeneous material under self-compression and adiabatic temperature gradient.

LLSVP Large low-shear-velocity province, used to describe broad regions beneath Africa and the South Atlantic and beneath the southern Pacific, which have anomalously low shear velocities, less pronounced compressional velocity decreases, sharp lateral boundaries, and indications of higher than average densities. These features have often been labeled superplumes, but the seismic data favor them being chemically distinct, dense piles of material possibly entrained by surrounding mantle flow.

P wave Elastic wave involving compressional and dilational motion of the medium as the wave propagates and the faster of the two seismic waves. Can transit both solid and fluid media.

S wave Elastic wave involving shearing motion of the medium with no volumetric change as the wave propagates and the slower of the two seismic waves. Can only transit solid media.

1.22.1 Lower Mantle and D″ Basic Structural Attributes

Earth's lower mantle is a thick layer of rock extending downward more than 2000 km from the transition zone to the core–mantle boundary (CMB) at an average depth of 2891 km. Seismology provides the basis for defining the lower mantle, as it was evident from the consideration of even the earliest global P-wave and S-wave travel time curves that this region of the interior has relatively smoothly increasing seismic velocities with depth, with an overall velocity gradient significantly reduced from that in the overlying transition zone.

The upper limit of the lower mantle has various definitions; many geophysicists associate it with the 650 km deep seismic velocity discontinuity, while others prefer to designate it at a greater depth of about 800 km, where there tends to be a reduction in radial velocity gradients in detailed seismic velocity models, as well as intermittent reports of a seismic discontinuity (e.g., Datt and Muirhead, 1976; Revenaugh and Jordan, 1991). The variety of phase transformations for upper mantle minerals olivine, enstatite, and garnet to their high-pressure polymorphs that characterize the transition zone all culminate in transitions to magnesium silicate perovskite [$(Mg,Fe)SiO_3$], ferropericlase [(Mg,Fe)O], and calcium perovskite [$CaSiO_3$]. The latter transitions should largely go to completion by about 800 km depth, which can thus be viewed as the base of the transition zone. The subsequent stability of the abundant magnesium silicate perovskite mineral over great pressure and temperature ranges is the probable explanation for the relatively smooth velocity gradients observed across the lower mantle, with self-compression and a nearly adiabatic thermal gradient resulting in smoothly increasing density, rigidity, incompressibility, and associated P-wave and S-wave seismic velocities down to near the CMB.

A few hundred kilometers above the CMB seismic velocities have more complex structure, with abrupt increases or discontinuities in velocity occurring in regions of relatively high seismic velocity, likely as a result of a phase transition from magnesium silicate perovskite to the postperovskite phase (Hirose, 2006; Murakami et al., 2004; Shim, 2008), along with enhanced lateral variations that indicate the presence of thermal and chemical heterogeneities in a boundary layer above the CMB (e.g., Garnero, 2000; Garnero and McNamara, 2008; Lay and Garnero, 2004; Trønnes, 2009). Based on the seismic evidence for inhomogeneity in the structure, the lowermost few hundred kilometers of the lower mantle is called the D″ region (harkening back to an early nomenclature in which the lower mantle was labeled the D shell and then subdivided into D′ and D″; see Bullen, 1949). At the base of the lower mantle, there are localized regions with very strong seismic velocity reductions that may be explained by the presence of a melt component or strong iron enrichment within the lower mantle rock. The CMB separates the silicate and oxide minerals of the lower mantle from the molten iron alloy of the core, with the contrasts in physical properties such as density, viscosity, and rigidity across the CMB being as large or larger than those at the surface of the Earth.

Despite its generally simple overall seismological structure, the lower mantle appears to be undergoing large-scale dynamic processes. These are revealed by second-order features of the seismological models that have only begun to be resolved over the past 30 years or so. The great pressures existing in the lower mantle suppress the sensitivity of seismic wave velocities to variations in temperature and composition, muting the detectable effects. Progress in imaging the few percent three-dimensional variations in seismic velocities is unveiling the dynamic complexity of the lower mantle and indicates regions of convective upwellings, downwellings, and large-scale chemical heterogeneities that may have accumulated over time in the deep mantle. While current understanding of the dynamic regime remains limited, it appears that the lower mantle plays a major role in regulating heat flux from the core, in cycling heat out of the interior, and in segregating chemical heterogeneities for long intervals of time, giving rise to geochemical anomalies observed at surface volcanic sites.

1.22.1.1 Elastic Parameters, Density, and Thermal Structure

P-wave and S-wave velocities and density increase smoothly across the lower mantle to the D″ region in all one-dimensional seismic velocity models for the Earth. **Figure 1** shows the variations in these properties as given by the Preliminary Reference Earth Model (PREM), which was based on a large number of body-wave travel times and free-oscillation eigenfrequencies (Dziewonski and Anderson, 1981). Below the abrupt seismic velocity and density increases near 650–670 km deep, which are primarily attributed to the dissociative phase transition of $(Mg,Fe)_2SiO_4$ γ-spinel (ringwoodite) to $(Mg,Fe)SiO_3$ perovskite plus (Mg,Fe)O ferropericlase (e.g., Ito and Takahashi, 1989; Ito et al., 1990; Yu et al., 2007), all the way down to the CMB, there are no abrupt changes in properties that demand global large-scale layering of the lower mantle (e.g., Green and Falloon, 1998). The bounds on the seismic velocity models given in **Figure 1** indicate the range of velocities that are admissible for one-dimensional models, based on observed travel time fluctuations for seismic body waves. The relatively tight range of velocity bounds indicate that if there are any velocity discontinuities in the deep mantle, they are less than a few percent or there are strong lateral variations in the depths of the structure such that it is not well represented by a one-dimensional model.

In fact, there are many studies inferring the presence of localized reflectors or scatterers in the depth range 650–1200 km depth (e.g., Kaneshima and Helffrich, 2009; Muirhead and Hales, 1980; Niu and Kawakatsu, 1997; Vinnik et al., 1998a), but the observations are intermittent, and there is, as yet, no agreed upon globally extensive discontinuity below 650-km depth that would be warranted in a one-dimensional Earth model. This fact is often invoked to support the idea that the lower mantle is chemically uniform, but one should keep in mind that chemical layering is likely to involve rather subtle changes in seismic velocities and details of the density structure are not well resolved by normal-mode observations. Thus, it is possible that the lower mantle is chemically stratified, perhaps with depth variations in Si or Fe content, with substantial topography on any chemical contrasts (e.g., Anderson, 1991, 1998; Kellogg et al., 1999; Murakami et al., 2012). Assessing this possibility requires consideration of three-dimensional velocity structures, but even then, it may

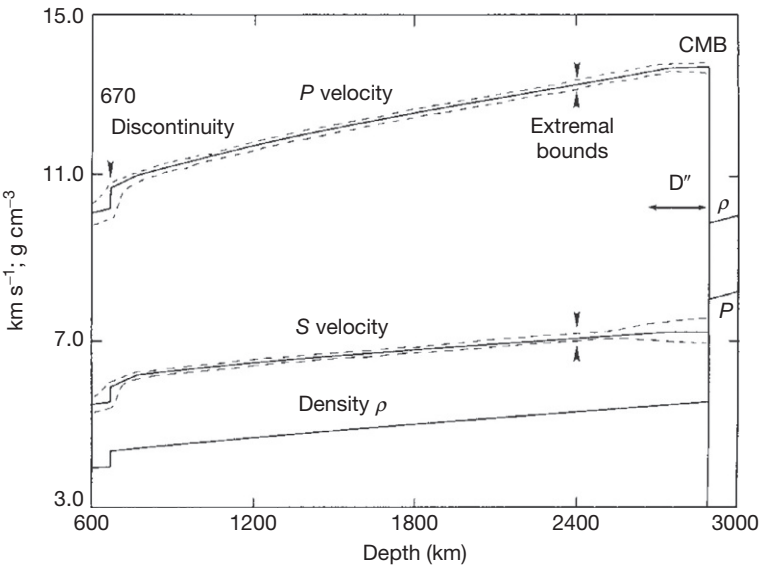

Figure 1 Variation of seismic velocities and density through the lower mantle for model Preliminary Reference Earth Model (PREM) (Dziewonski and Anderson, 1981), along with the extremal bounds that indicate the confidence intervals for spherically averaged models based on travel time data (Lee and Johnson, 1984). The D″ region is the lowermost 200–300 km of the lower mantle overlying the core–mantle boundary (CMB). Reproduced from Lay T (1989) Structure of the core–mantle transition zone: A chemical and thermal boundary layer. *Eos*, *Transactions of the American Geophysical Union* 70: 49, 54–55, 58–59.

be difficult because velocity discontinuities associated with any chemical contrasts are likely to be relatively small.

The bounds on one-dimensional S-wave velocity models tend to flare in the lower 300 km of the mantle, indicating larger variability in S-wave travel times for waves traversing the D″ region above the CMB. In this region, seismic waveform modeling has resulted in localized velocity models with 1–3% abrupt increases in shear velocity and large-scale regions with 3–6% low shear velocity. There is no average one-dimensional model that represents the D″ structure well, and the lateral variations must be characterized with three-dimensional structures in order to assess their significance. P-wave observations also indicate abrupt increases in P-wave velocity in some regions, but in general, the P-wave structure is less heterogeneous than for S waves. At the very base of the lower mantle, within tens of kilometers above the CMB, there are localized regions with very pronounced reductions in both P-wave velocity and S-wave velocity, which are called ultralow velocity zones (ULVZs). ULVZs may represent a transition zone from mantle to core, but they must be undetectably thin (<∼5 km) or not present in many regions.

1.22.1.2 Mineralogical Structure

The composition and mineralogy of the lower mantle is not directly determined from seismic observations and must be deduced based on models for the bulk composition of the Earth along with experimental and theoretical mineral physics that reproduces observed density and elastic velocity profiles for appropriate pressures and temperatures. Given the experimental determination of stability of the magnesium silicate perovskite phase (Liu, 1974) as the polymorph of predominant upper mantle minerals subjected to lower mantle conditions, along with the chondritic Earth model, there is high confidence that $(Mg_x,Fe_{1-x})SiO_3$ perovskite is the primary mineral form in the lower mantle (e.g., Fiquet et al., 2000; Gong et al., 2004; Knittle and Jeanloz, 1987; Shim et al., 2001, 2004; Wentzcovitch et al., 2004). The value of x (the magnesium number) is probably in the range 0.8–0.9, although some aluminum substitution is very likely to exist in lower mantle perovskites as well. The experimental and chondritic model constraints on mineralogy also favor the presence of $(Mg_x,Fe_{1-x})O$, with x again in the range 0.8–0.9 overall, although it could be much lower in some cases, as well as some Ca perovskite. Other minor phases are likely to exist, but constraints on their abundance are very limited.

Extensive theoretical and experimental mineral physics research continues to characterize the equations of state, effects of minor components like Al, element partitioning, and physical properties of the following primary lower mantle minerals (or low-pressure analog minerals): *magnesium silicate perovskite* (e.g., Aizawa and Yoneda, 2006; Andrault et al., 2007; Auzende et al., 2008; Boffa Ballaran et al., 2012; Carrez et al., 2007a; Cordier et al., 2004; Deng et al., 2008; Dorfman et al., 2012; Ferré et al., 2007; Irifune et al., 2010; Ito and Toriumi, 2010; Jackson and Kung, 2008; Jackson et al., 2005; Jung et al., 2010; Katsura et al., 2009; Lundin et al., 2008; Miyajima et al., 2009; Mosenfelder et al., 2009; Murakami et al., 2007a; Nishio-Hamane et al., 2008; Nishiyama et al., 2007; Ono et al., 2006a,b; Panero et al., 2006; Ricolleau et al., 2009; Saikia et al., 2009; Sakai et al., 2009a; Tange et al., 2009, 2012; Vanpeteghem et al., 2006a,b; Xu et al., 2011; Yamazaki et al., 2009), *MgO and ferropericlase* (e.g., de Koker, 2010; Fukui et al., 2012; Gleason et al., 2011; Jackson et al., 2006; Komabayashi et al., 2010; Marquardt et al., 2009b; Murakami et al., 2009; Speziale et al., 2007a,b;

Tsujino and Nishihara, 2010; Wu et al., 2008), and *calcium perovskite* (e.g., Adams and Oganov, 2006; Jung and Oganov, 2005; Kojitani et al., 2009; Komabayashi et al., 2007; Kudo et al., 2012; Li et al., 2006b,c; Miyagi et al., 2006, 2009; Stixrude et al., 2007; Sueda et al., 2006).

Transport properties for the major minerals such as electrical conductivity are also being addressed (e.g., Ono et al., 2006b; Tarits and Mandéa, 2010; Velimsky, 2010). With the possibility of lithospheric slabs sinking into the lower mantle, the deep mantle properties for mid-ocean ridge basalt (MORB) compositions (in the high-pressure eclogitic phase and in lower mantle polymorphs) are also being explored (e.g., Hirose et al., 2005a; Kono et al., 2007; Mookherjee, 2011; Ohta et al., 2008a, 2010b; Ricolleau et al., 2010; Tsuchiya, 2011). Other minor phases such as poststishovite (e.g., Bolfan-Casanova et al., 2009; Lakshtanov et al., 2007; Nomura et al., 2010; Wang et al., 2012) and various carbonates (e.g., Boulard et al., 2012; Lavina et al., 2009, 2010; Litasov et al., 2008; Mao et al., 2011a; Oganov et al., 2006, 2008) are likely to exist in the lower mantle, but constraints on their small abundances are very limited. This huge outpouring of experimental and theoretical mineral physics results reflects great advances made in the last decade in both laboratory measurements and first-principles computations of mineral phase equilibriums and material properties. Comparisons of predictions with seismic observations are still not uniquely diagnostic of the lower mantle composition due to many trade-offs and uncertainties in mineral composition, accompanied by new discoveries in material properties (e.g., Matas et al., 2007).

Recent experimental and first-principles work (Badro et al., 2003, 2004; Hofmeister, 2006; Li et al., 2004, 2005; Lin and Tsuchiya, 2008; Lin et al., 2005; Speziale et al., 2005; Sturhahn et al., 2005; Zhang and Oganov, 2006) has established that at high pressure, Fe, normally in its high-spin state for both Fe^{2+} and Fe^{3+} in perovskite and ferropericlase in the shallow lower mantle, will prefer to be in a denser, low-spin state in the lowermost mantle. This so-called spin transition can influence thermal, electric, elastic, and viscous properties of the lower mantle, and there has been a huge surge of research in the past few years to characterize the attributes of the iron spin transition and its implications. Computational and experimental efforts are quantifying the spin crossovers in *ferropericlase* (e.g., Ammann et al., 2011; Antonangeli et al., 2011; Cammarano et al., 2010; Chen et al., 2012a,b; Crowhurst et al., 2008; Fei et al., 2007; Kantor et al., 2006; Lin et al., 2006a,b, 2007a,b; Mao et al., 2011a,b; Persson et al., 2006; Saha et al., 2011, 2013; Speziale et al., 2007b; Tsuchiya et al., 2006a,b; Wentzcovitch et al., 2009; Wu et al., 2009; Yoshino et al., 2011) and *magnesium silicate perovskite* (Bengtson et al., 2008, 2009; Caracas et al., 2010; Catalli et al., 2010b, 2011; Fang and Ahuja, 2008; Fujino et al., 2012; Grocholski et al., 2009; Hsu et al., 2010, 2011; Li et al., 2006a; McCammon et al., 2008, 2010; Narygina et al., 2011; Nomura et al., 2011; Stackhouse et al., 2006b, 2007; Umemoto et al., 2008, 2010).

Implications of the spin transition for mixing dynamics and plume formation are also being considered (e.g., Bower et al., 2009; Shahnas et al., 2011), as well as effects on electrical conductivity (Ohta et al., 2007, 2010a). The various studies are not in full agreement, but most favor substantial pressure ranges for the various spin transitions and relatively subtle effects on seismic velocities, making it difficult to directly confirm the presence of spin transitions with seismic observations.

Properties of melts in the lower mantle are critical to understanding mantle chemical evolution, and theoretical and experimental studies have addressed issues of melt density and iron fractionation and Si and O partitioning between liquids and perovskite and ferropericlase in the deep mantle (e.g., de Koker and Stixrude, 2009; de Koker et al., 2013; Fiquet et al., 2010; Frost et al., 2004; Liebske and Frost, 2012; Mosenfelder et al., 2007; Seagle et al., 2008; Stixrude et al., 2009; Terasaki et al., 2007; Zhang and Fei, 2008; Zhang and Guo, 2009).

When one considers the mineralogy of the lower mantle, it is essential to keep in mind that there has undoubtedly been extensive chemical processing, melting, and mixing. This would have occurred during the energetic processes of accretion and core formation, as a result of early large impacts, and as an ongoing consequence of mantle convection and chemical differentiation involving crustal formation and recycling. The huge density increase at the CMB, larger than that at Earth's surface, provides an environment favorable for the accumulation of dense silicate and oxide materials, a region toward which dense iron-rich materials may settle, and a chemically active environment in which mantle rocks and core alloys may exchange elements over time. Geophysical constraints on the precise mineralogy and chemistry are quite limited, and we lack direct access to samples of lower mantle rocks, so various mineralogical scenarios for the lower mantle, particularly for minor components, can be considered as long as they are shown to agree overall with the seismological information available for the region. While high viscosity of the lower mantle may allow chemical heterogeneities to persist for long intervals of time, the notion of a primitive, unprocessed lower mantle composition is at odds with prevailing notions of Earth's formation and evolution. Presumably huge amounts of iron have separated from the mantle, and there has been extensive melting, which likely would lead to volatile depletion of the deep mantle and chemical stratification that may or may not have survived subsequent entrainment.

1.22.2 One-Dimensional Lower Mantle Structure

The most direct constraints on lower mantle structure are provided by seismic waves that traverse the interior. The main observables of importance are the travel times of P waves and S waves, any waveform complexities arising from interactions with contrasts in properties in the rocks, S-wave splitting produced by anisotropy, and frequency-dependent amplitude behavior of the seismic waves that can constrain the anelasticity of the lower mantle. The average lower mantle seismic velocities have been determined by both classical arrival time inversion and normal-mode analysis, with the latter also refining early estimates of the density structure that had been based on velocity–density systematics, integral constraints provided by Earth's mass and moment of inertia, and piecewise integration of seismic velocity models using the Adams–Williamson equation (Adams and Williamson, 1923). With the early

recognition of the general simplicity of lower mantle structure, most research prior to 1980 focused on developing robust one-dimensional models for lower mantle structure.

1.22.2.1 Body-Wave Travel Time and Slowness Constraints

Observations of travel times of seismic waves at varying distances from earthquake and explosion sources for which the source locations and origin times are either known or solved for are plotted in travel time curves, as shown for shallow focus events in Figure 2. This classic display of seismic observations immediately reveals two defining attributes of the Earth: The deep structure must be largely radially symmetrical, as that is required for having tightly defined travel time branches for each path through the Earth, and the travel times of major phases such as P, PP, S, and SS are smoothly increasing functions in the angular distance (Δ) range 30–100°, which corresponds to the range where the seismic wave fronts turn in the lower mantle. The smooth, continuous curves obtained by fitting the observations can be inverted for one-dimensional models of seismic velocity versus depth using classic methods such as the Herglotz–Wiechert inversion or by computer modeling (see Lay and Wallace, 1995). The slope of a travel time curve at a given angular distance, $\Delta T/\mathrm{d}\Delta$, gives the seismic ray parameter and its inverse the apparent velocity. These are related to the geometry of the wave front as it sweeps through the Earth and the velocity at the depth in the Earth where the wave turns back toward the surface causing it to arrive at a particular distance. The smooth, concave downward curvature of P-wave and S-wave travel time curves beyond 30° directly implies smoothly increasing velocities with depth in the lower mantle. The ray parameter can be estimated either from a smoothed travel time curve or by direct measurement of relative arrival times of a given seismic phase across an array of closely spaced receivers.

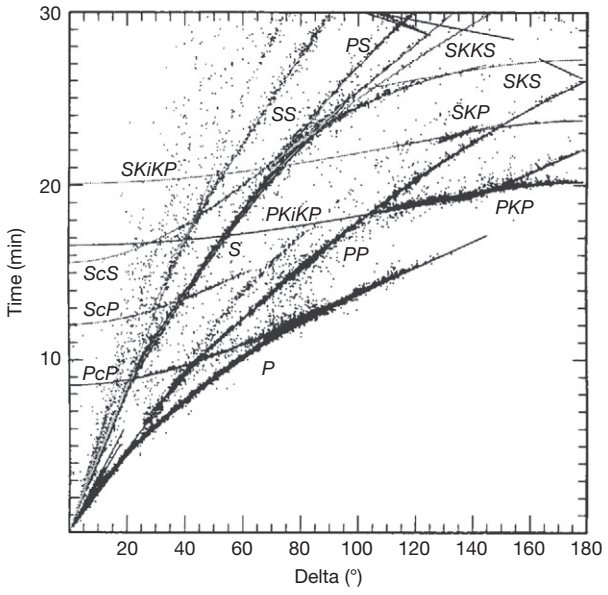

Figure 2 Observed travel time measurements for P and S seismic phases as a function of epicentral distance in the Earth for shallow earthquake sources, along with the predicted (labeled) travel time curves for a radially symmetrical model of P-wave and S-wave velocity variations with depth. P and S are direct phases: PcP, ScP, and ScS reflect from the core–mantle boundary; PKiKP and SKiKP reflect from the inner core–outer core boundary; PP, SS, and PS reflect once from Earth's surface; and PKP, SKP, SKS, and SKKS are phases that traverse Earth's core. Reprinted from Kennett BLN and Engdahl ER (1991) Travel times for global earthquake location and phase identification. *Geophysical Journal International* 105: 429–465, with permission from the Royal Astronomical Society.

Global observations of body-wave travel times and measurements of slopes of the travel time curves by seismic array analyses proliferated in the 1960–1990s, with many radially symmetrical Earth models for the lower mantle being produced (e.g., Chinnery and Toksöz, 1967; Dziewonski and Anderson, 1981; Hales and Roberts, 1970; Hales et al., 1968; Herrin, 1968; Johnson, 1969; Kennett and Engdahl, 1991; Morelli and Dziewonski, 1993; Randall, 1971; Sengupta and Julian, 1978; Uhrhammer, 1978). While the variations in lower mantle velocities at a given depth among these models are $<1\%$, there is still great importance in having an accurate reference model both for earthquake location procedures and for use as a background model in tomographic analyses. Thus, efforts to improve the average lower mantle parameters continue, with increasing quantities of data and variety of phase types being incorporated into the analysis (Masters et al., 1999). All of these one-dimensional lower mantle models have smooth velocity gradients like those in the PREM model (Figure 1).

The small variations between lower mantle radial velocity models have still received much attention because any departure from homogeneity (as expected for self-compression of uniform composition material) would have major implications for possible chemical layering or phase changes. P and S velocities throughout the lower mantle above the D″ region are bounded to within about $\pm 0.1\ \mathrm{km\ s^{-1}}$ in terms of an average model (e.g., Lee and Johnson, 1984). This tight bound (Figure 1) is consistent with the finding by Burdick and Powell (1980) that small features in ray parameter estimates from seismic arrays tend to vary azimuthally, but are not globally representative, with on average very smooth structure in the lower mantle being preferred for a one-dimensional model. There have been observations of reflections and converted phases from a velocity or impedance contrast near 900 km depth near subduction zones (e.g., Kawakatsu and Niu, 1994; Revenaugh and Jordan, 1991), but this appears to be a strongly laterally varying structure (Shearer, 1993) and may be associated with steeply dipping mantle heterogeneities that are likely associated with deeply penetrating subducted slabs (Castle and Creager, 1999; Kaneshima, 2009; Kaneshima and Helffrich, 1998, 2009; Niu and Kawakatsu, 1997; Vanacore et al., 2006; Vinnik et al., 1998a). Reports of arrivals reflected or scattered from other depths in the upper third of the lower mantle are numerous (Courtier and Revenaugh, 2008; Courtier et al., 2007; Kito et al., 2008; Rost et al., 2008; Vinnik et al., 2010), but at this time, there is no compelling evidence for significant laterally extensive layering of the lower mantle except near the top of the D″ region.

1.22.2.2 Surface-Wave/Normal-Mode Constraints

In addition to body-wave travel times, measurements of normal-mode eigenfrequencies play a major role in defining one-dimensional seismic velocity and, most importantly, density models for the lower mantle (see also **Chapter 1.04**). Normal modes correspond to standing patterns of P-wave and S-wave motions and provide constraints on the structure appropriate for relatively long-period motions compared to body-wave arrival times. The motions of normal modes involve large volumes of rock, and the varying depth sensitivity of different modes readily allows for the construction of one-dimensional models of the lower mantle. The large-scale motions allow the density structure to be sensed as well, particularly when a variety of modes are analyzed together to obtain velocity and density models. Important early one-dimensional models for lower mantle structure based largely on normal-mode observations include those of Jordan and Anderson (1974), Gilbert and Dziewonski (1975), Dziewonski et al. (1975), and Dziewonski and Anderson (1981). These models are compatible in basic structure with those obtained from body-wave analyses, but it was observed early on that there is some difference in absolute velocities between body-wave and normal mode-based models. In the late 1970s, this baseline discrepancy was recognized to be the effect of dispersion due to intrinsic attenuation as waves traverse the Earth. Attenuation causes shorter-period signals to sense slightly higher seismic velocities than longer-period signals. The development of phenomenological models for attenuation in the mantle allows an anelastic Earth model, such as PREM (**Figure 1**), to vary systematically in velocity as a function of wave period, reconciling body-wave and normal-mode observations (e.g., Anderson et al., 1977; Dziewonski and Anderson, 1981; Kanamori and Anderson, 1977; Liu et al., 1976).

By far, the most important contribution to lower mantle structure from normal modes is the resolution of density structure. Body-wave travel times provide indirect sensitivity to density, and only through the use of the Adams–Williamson approach can body-wave seismic velocities be used to infer the density structure (reflected and converted phases can provide some information on density contrasts at internal boundaries). The large volume of rock in motion during normal-mode oscillations provides direct sensitivity to gravitational effects on the waves and hence to density. Thus, the development of one-dimensional seismic models from normal-mode observations explicitly involves density structure. As for the seismic velocity models, the density structure in the lower mantle involves simple increase with depth (**Figure 1**), with density increasing from about $4.8\,\mathrm{g\,cm^{-3}}$ at 800 km depth to $5.56\,\mathrm{g\,cm^{-3}}$ just above the CMB. The normal-mode sensitivity is limited in terms of resolving any small discontinuities but can bound the absolute levels over several hundred kilometer thickness to less than about 0.5% uncertainty for a one-dimensional model. This places some constraint on the degree of admissible lower mantle layering due to chemical density differences, although the likelihood that any deep layering may have large topographic variations induced by mantle flow complicates the interpretation of such normal-mode constraints.

1.22.2.3 Attenuation Structure

The Earth is not perfectly elastic, and as seismic waves travel through the interior, they undergo anelastic attenuation that gradually diminishes their amplitudes at a rate greater than that caused by geometric spreading. The mechanisms responsible for anelastic losses are generally thermally activated microscale processes such as dislocation motions and grain boundary interactions (e.g., Anderson, 1967; Minster, 1980; Minster and Anderson, 1981). Lacking resolution of the microscale processes, seismologists use phenomenological models that account for the macroscopic effects of anelasticity, parameterizing the corresponding departures of wave behavior from that for a purely elastic medium. The most common parameterization of attenuation is in the form of a quality factor, Q, defined as the inverse of the fractional loss of energy, E, per cycle of oscillation: $1/Q = -\triangle E/(2\pi E)$. Lower values of Q correspond to stronger anelastic loss or more attenuation. Infinite Q would correspond to elastic behavior. The finite Q encountered by a seismic wave in the lower mantle may vary from frequency to frequency because different mechanisms are activated for different timescales. Over a finite range of frequencies, there will be a dispersive effect, with higher frequencies sensing an unrelaxed effective modulus relative to lower frequencies. This results in physical dispersion, the reason that short-period body waves sense slightly higher seismic velocities than long-period normal modes. The magnitude of this effect depends on the absolute value and frequency dependence of Q appropriate for a given wave motion.

The lower mantle has relatively high Q values for seismic waves, and determining the structure is rather difficult due to regional variations of strong attenuation in the overlying upper mantle that must be traversed by all wave motions observed at the surface. Normal modes and averaged body-wave attenuation measurements place some constraints on the average Q values, but it is possible to satisfy most data with extremely simple models (e.g., Anderson and Hart, 1978; Dziewonski and Anderson, 1981; Masters and Gilbert, 1983; Widmer et al., 1991). For example, the PREM model has S-wave quality factor, $Q_\mu = 312$, throughout the lower mantle, while P-wave quality factor, Q_α, increases from 759 at 670 km depth to 826 at the CMB. While there is some evidence for a low-Q zone at the base of the mantle, this is not well resolved because of strong trade-offs with velocity gradients in the D″ region. The detailed frequency dependence of attenuation in the lower mantle is not yet well resolved, and there have been some recent efforts to develop new attenuation models for the lower mantle (e.g., Ford et al., 2012; Hwang and Ritsema, 2011; Lawrence and Wysession, 2006).

To give a sense for the anelastic dispersive effect associated with lower mantle structure, we consider the PREM S-wave velocities at a depth of 2271 km for periods of 1 s ($7.055\,\mathrm{km\,s^{-1}}$) and 200 s ($7.017\,\mathrm{km\,s^{-1}}$). The respective P-wave velocities are 13.131 and $13.103\,\mathrm{km\,s^{-1}}$. The dispersive effects are small but physically must be present. Over long path lengths in the attenuating lower mantle, the small velocity differences integrate to give observable differences in body-wave and normal-mode observations that have to be accounted for. Thus, a realistic one-dimensional model of the

lower mantle must include a seismic wave attenuation structure, and that intrinsically leads the velocity model to have frequency dependence. PREM is the primary one-dimensional model with this physical dispersion explicitly being included, although Montagner and Kennett (1996) considered frequency-dependent effects. Other single-frequency models, such as ak135 (Kennett et al., 1995), have improved the travel time fit to certain seismic phases, notably core phases, but such models have not explicitly been reconciled across a broad frequency range so they are useful for earthquake location procedures, but not as a Earth model for interdisciplinary applications.

1.22.3 Three-Dimensional Lower Mantle Structure

One-dimensional Earth models are remarkably successful in predicting seismic wave travel times for paths traversing the lower mantle, typically accurate within a fraction of a percent for teleseismic P and S waves. This is a manifestation of the importance of gravity and chemical differentiation in producing a strongly radially stratified planet. Nonetheless, there are observable systematic travel time fluctuations at a given distance range that indicate deviations from a one-dimensional structure. Such fluctuations are particularly evident for waves traversing only the crust and upper mantle, where there are relatively strong heterogeneities. After suppressing the contributions from strong upper mantle heterogeneity either by using laterally varying models or by computing differential travel times between phases observed at a given station, the scatter in P-wave travel times relative to predictions for a one-dimensional lower mantle model is generally within $\pm$1–2 s (for paths with travel times of 600–700 s), while for S waves, scatter is typically $\pm$4–6 s (for paths with travel times of 1000–1200 s). There are some regions like that in the lowermost mantle under Africa and the central Pacific, with late S-wave arrival time anomalies of up to 15–20 s attributed to particularly anomalous lower mantle paths (e.g., Ni and Helmberger, 2003a). These variations in travel times indicate that minor aspherical elastic velocity structure exists in the lower mantle, and many seismological studies have attempted to constrain either global or regional heterogeneities in the lower mantle.

1.22.3.1 Seismic Tomography

Initial investigations of aspherical structure in the lower mantle utilized moderate-sized (hundreds to a few thousand) sets of travel time anomalies (e.g., Sengupta and Toksoz, 1976) or differential travel time observations (e.g., Jordan and Lynn, 1974; Lay, 1983) to detect systematic variations relative to standard one-dimensional models. The main challenges in resolving lower mantle heterogeneity involve the uncertainty in earthquake source locations (typically, these are approximated by solving the location problem assuming a one-dimensional velocity structure, which intrinsically leads to an incorrect location estimate and consequent artifacts in the residual arrival times) and the strength of upper mantle heterogeneities (particularly near-source structures such as subducting slabs). These remain vexing problems, and it is reasonable to believe that current estimates of deep mantle heterogeneity are still biased by incomplete suppression of event location effects and upper mantle heterogeneities. While strategies such as computing differential time anomalies (e.g., ScS-S, SKS-S, or PcP-P differential arrival times relative to one-dimensional model predictions are commonly used) can reduce source mislocation and near-source and near-receiver structural effects due to the similarity of the ray-paths for the two phases in these regions, it remains possible that failure to account for strong lateral gradients in shallow structure causes erroneous interpretation of differential time anomalies as being due to deep mantle heterogeneity. The long-term solution to this problem is the development of very accurate models for upper mantle structure (including 3D slab and mid-ocean ridge structures) used in a self-consistent way with event locations. In general, this is still not done in most of today's large-scale tomographic inversions, but progress is gradually being made toward this goal (see also **Chapters 1.06** and **1.09**).

Given large numbers of observations of seismic phases with good azimuthal and ray parameter coverage from an earthquake, the effects of source mislocation can be suppressed even if a one-dimensional model or low-resolution upper mantle aspherical model is used. This can never be a perfect process unless one invokes precise a priori near-source information (the process of estimating the origin time always removes a baseline term from the travel times leading to anomalies with fluctuating sign even when the true anomalies should be one-sided). Seismic tomography uses the arrival time anomalies from many source–receiver combinations to invert for a parameterized version of mantle heterogeneity, ideally for well-sampled event populations where location effects are suppressed by coverage. In this case, the crossing coverage from multiple paths can build up the image of spatially varying velocity structure, although in almost every case, the amplitude of the actual heterogeneity will be intrinsically underestimated by the inversion model. This is the primary approach to imaging lower mantle heterogeneity on large and small scales; although the requirement of well-resolved source locations is seldom met in practice, approximations in ray tracing are commonly made, and iteration to attain self-consistent event locations and aspherical models is performed in only a minority of studies (e.g., Mégnin and Romanowicz, 2000). All results of lower mantle seismic tomography must thus be viewed as having limited resolution at this time, and there is significant inconsistency in small-scale structures between models. Even with these limitations, the implications of the current generation of models are profound.

One of the earliest fundamental contributions of global seismic tomography was the demonstration that coherent structure exists in the lower mantle on scale lengths of several thousand kilometers and that this unexpected configuration of large-scale deep heterogeneity can account for previously unexplained long-wavelength features in Earth's geoid (e.g., Clayton and Comer, 1983; Dziewonski, 1984; Dziewonski et al., 1977; Hager et al., 1985; Masters et al., 1982). Establishing this connection required both the development of global models and the improved understanding of how mantle heterogeneities induce flow and deflection of boundaries that affect the geoid (Hager, 1984; Richards and Hager, 1984). While the early low-resolution tomographic models for the lower mantle have relatively strong spherical harmonic components from degrees 2 to 5, and proved remarkably successful

in accounting for the long-wavelength geoid (see review by Hager and Richards, 1989), there has been continuing debate about the spectrum of lower mantle heterogeneity. Are the long-wavelength patterns the result of truly diffuse structures or are they in part due to smoothed sampling of smaller scale but very heterogeneous features such as slabs embedded in the lower mantle? If the latter is the case, the long-wavelength distribution of heterogeneity in the lower mantle is more a consequence of the last few hundred million years of surface tectonics and associated plate subduction than a very long-term aspect of the lower mantle convective regime (e.g., McNamara and Zhong, 2005). Similarly, if the long-wavelength patterns in surface hot spots reflect swarms of thermal plumes rising from the CMB, then the distribution of recent D″ boundary layer instabilities may contribute to the present long-wavelength structure of the deep mantle.

Imaging of deep mantle structure has advanced in resolution by steadily increasing the size and raypath coverage of the data sets and by using improved measurement and inversion approaches. There is significant convergence in large-scale structures in recent deep mantle tomographic shear velocity models (e.g., Antolik et al., 2003; Grand, 2002; Grand et al., 1997; Gu et al., 2001; Houser et al., 2008; Kustowski et al., 2008; Lekic et al., 2012; Li and Romanowicz, 1996; Liu and Dziewonski, 1998; Masters et al., 1996, 2000; Mégnin and Romanowicz, 2000; Panning and Romanowicz, 2006; Panning et al., 2010; Ritsema et al., 1999, 2011; Simmons et al., 2007, 2009, 2010; Takeuchi, 2007), all of which have dominant long-wavelength heterogeneities. The same is true for large-scale P velocity models, although there is still less agreement between models and somewhat less complete coverage of lower mantle regions (e.g., Antolik et al., 2003; Bijwaard and Spakman, 1999; Bijwaard et al., 1998; Boschi and Dziewonski, 1999, 2000; Fukao et al., 1992, 2001; Houser et al., 2008; Karáson and van der Hilst, 2001; Lei and Zhao, 2006; Li et al., 2008; Myers et al., 2011; Simmons et al., 2011, 2012; van der Hilst and Kárason, 1999; Vasco and Johnson, 1998; Widiyantoro and van der Hilst, 1996; Zhao, 2001).

As the resolution of large-scale lower mantle 3D structure has improved with each new generation of global tomographic models, it has become clear that there are significant intermediate-scale features in the lower mantle. This had previously been deduced for localized regions by array studies or by analyses of differential travel times for phase pairs sensitive to lower mantle structure (e.g., Jordan and Lynn, 1974; Lay, 1983), but the geometry and lateral extent of such features could not be resolved until large-scale tomographic models were produced. Recent high-resolution S-wave velocity (e.g., Grand, 2002; Simmons et al., 2010) and P-wave velocity (Ren et al., 2007; van der Hilst et al., 1997) models resolve a high-velocity quasitabular structure extending nearly vertically in the lower mantle beneath North America and South America and a similar elongate body beneath southern Eurasia, both of which extend to at least 1300–1600 km depth (**Figure 3**). The width of these features is not tightly resolved, but appears to be at least 500 km, and the anomalies are 1–2%, which is relatively high for this depth range in the mantle. These features are usually interpreted as relatively cold, sinking slab material that has penetrated into the lower mantle as the Americas moved westward and as the Tethys Sea closed, respectively. The aspherical seismic velocity structure in the mid-mantle near 1300 km depth is dominated by these elongate tabular high-velocity features, and it is likely that these contribute significantly to the strong long-wavelength patterns in spherical

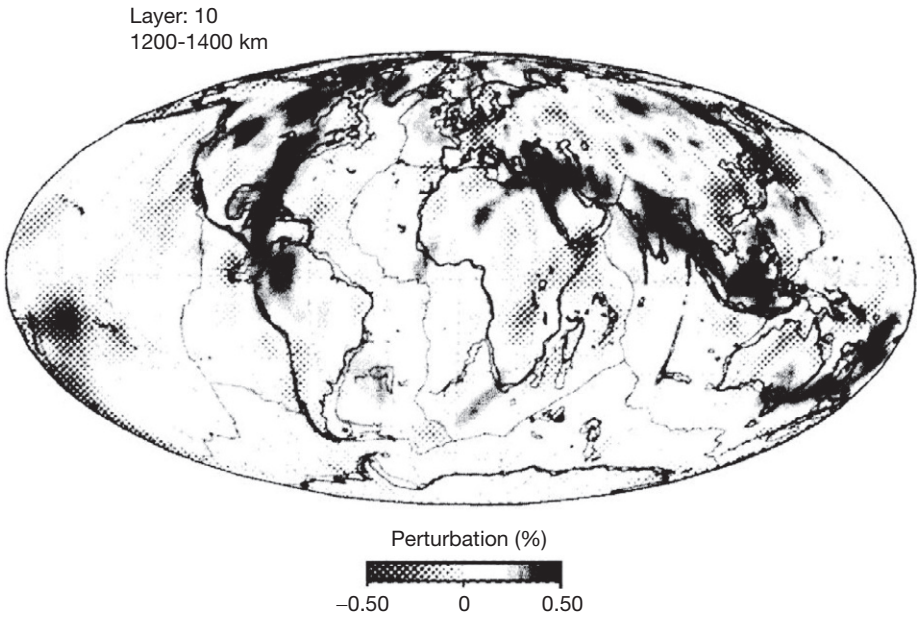

Figure 3 Horizontal section through a tomographic model of P-wave velocity structure near 1300 km deep in the lower mantle, obtained by inversion of ISC arrival times after careful processing for depth determination. Solid dark areas correspond to relatively high velocities, with two major coherent features that correspond to tabular structures extending semivertically below southern Asia and eastern North America. These are inferred to be subducted slab material that has penetrated into the lower mantle. Reproduced from van der Hilst RD, Widiyantoro S, and Engdahl ER (1997) Evidence for deep mantle circulation from global tomography. *Nature* 386: 578–584.

harmonic models that have lower resolution (see corresponding features in the early lower-resolution models discussed by Dziewonski et al., 1993). While there may be contributions to these structures from inadequately suppressed shallow mantle structures, particularly strong near-source slab anomalies, the high-velocity regions do appear in models with different data sets, different model parameterizations, and varying source–receiver geometries, so it is very difficult to dismiss them as artifacts.

Below about 1600 km depth, tomographic models show less coherence, relatively weak velocity anomalies, and tabular structures are not clearly imaged (e.g., Grand et al., 1997; Simmons et al., 2012). Instead, the models tend to become dominated by horizontally extensive regions of high and low velocity with strong degree 2 and 3 patterns in the lowermost mantle (Figure 4). The strength of the velocity heterogeneity increases in the lowermost 300–500 km of the mantle, particularly for shear waves (Figure 5). Lateral variations of ±4% in S-wave velocity and ±1.5% in P-wave velocity are observed. High shear velocities in the lowermost mantle are found beneath circum-Pacific margins, although only in a few places is there apparent continuity of high-velocity features from the mid-mantle all the way to the CMB. The aspherical S-wave velocity models all display two large low-shear-velocity provinces (LLSVPs) located below the central Pacific and the southern Atlantic/southern Africa/southern India Ocean region. The latter two low-velocity regions appear to extend upward above the D″ region, possibly as much as 800–1000 km. These features have sometimes been called 'superplumes,' given than their scale greatly exceeds that expected for isolated D″ boundary layer instabilities, and Dziewonski et al. (1993) called them the 'Equatorial Pacific Plume Group' and the 'Great African Plume,' respectively. Attributing dynamic significance to these features with the 'plume' label is complicated and very uncertain; low velocities may be caused by high temperatures or by chemical differences. It is preferable to use the dynamically neutral label of LLSVPs, as discussed later.

1.22.3.2 Dynamic Structures

While the geoid and some attributes of subduction zone morphology provide geodynamic constraints on lower mantle dynamics, most of what we know about dynamic processes in the deep Earth derives from interpretations of seismic tomography. This is not a trivial undertaking because there are limitations in the spatial resolution of the tomographic models and possible contributions from both thermal and chemical heterogeneities that are difficult to separate. Any

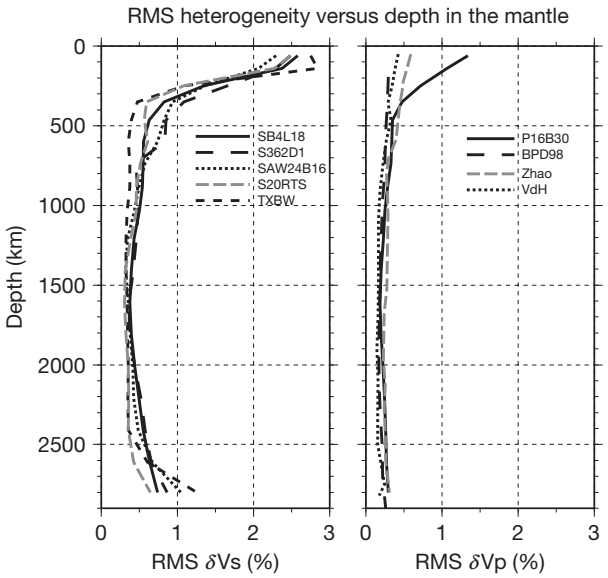

Figure 5 RMS velocity fluctuations at various depths in the mantle shear velocity models SB4L18 (Masters et al., 2000), S362D1 (Gu et al., 2001), SAW24B16 (Mégnin and Romanowicz, 2000), S20RTS (Ritsema and van Heijst, 2000), and TXBW (Grand, 2002) and in the mantle compressional velocity models P16B30 (Bolton, 1996), BPD98 (Boschi and Dziewonski, 1999), Zhao (Zhao, 2001), and VdH (Karáson and van der Hilst, 2001).

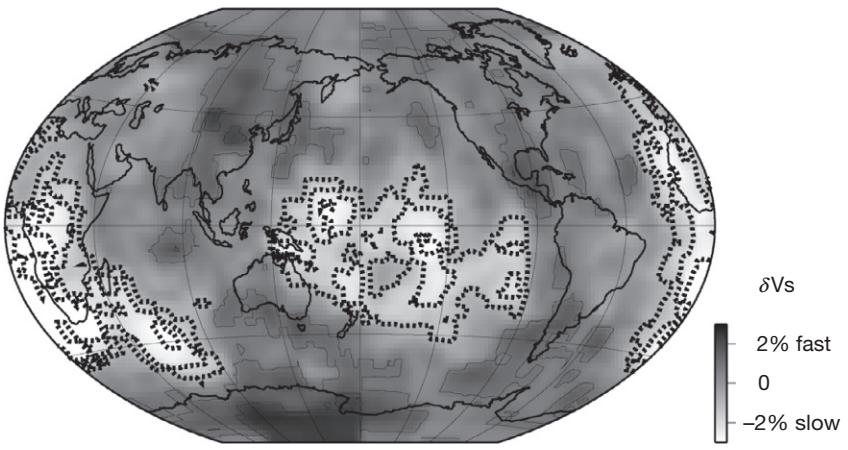

Figure 4 Representative large-scale mantle tomography for S-wave velocity structure (Grand, 2002) near the base of the mantle. Note the long-wavelength patterns of high velocities beneath the circum-Pacific and low velocities beneath the central Pacific and Africa. 1% contours are shown, with dotted lines highlighting the internal variations in the two large low-shear-velocity provinces. Variations of ±3% are imaged by this and other models with similar spatial patterns. Note the contrast in scale length of predominant heterogeneities with the mid-mantle pattern in Figure 3.

interpretation of tomography requires a foundation in mineral physics characterization of material property dependence on temperature and composition for the high-pressure conditions of the deep Earth. It also requires geodynamic analysis to assess the deformation processes taking place, guided by the seismological and mineral physics constraints on structure.

Seismological resolution of overall lower mantle structure has to be achieved by using different data types that provide distinct control on spatial and depth variations of structure. Overtones and multiple surface reflections provide sampling of structure near and below the transition zone, direct body-wave phases including core phases provide spatially nonuniform sampling of deep mantle corridors, diffracted waves extend coverage of structure near the CMB, and normal modes provide control on the large-scale even harmonics of the structure. One of the main challenges is that differences in how inversions of various data sets are regularized have large effects on how structural characterizations are interpolated and extrapolated in the various models (e.g., Boschi and Dziewonski, 1999). The very large-scale, degrees 2 and 3 patterns of heterogeneity are pronounced and well resolved now, and one of the key issues is whether weaker shorter-wavelength features are independent of or linked to the causes of the long-wavelength patterns.

While the lower mantle does not appear to have pronounced internal layering, it has been proposed that the downward transition in heterogeneity pattern from a mid-mantle dominated by slablike structures to a deep mantle dominated by large-scale high-velocity and low-velocity features is caused by compositional stratification. The stratification could be in a thin layer essentially confined to D″ (e.g., Davies and Gurnis, 1986) or in a much thicker layer. In the latter model (see Kellogg et al., 1999; van der Hilst and Kárason, 1999), the lowermost mantle is compositionally distinct, being composed of undifferentiated, possibly 'primordial' mantle material that is then invoked as the source of isotopic anomalies sampled by upwelling thermal plumes that produce distinctive surface hot spot volcanism. Downwelling slabs can depress the conjectured chemical boundary by hundreds of kilometers, deflecting it from a depth of around 2000 km. The chemical boundary is not expected to be a strong reflector and does not give rise to coherent features in the radially averaged mantle model. The density increase of the deep layer could be due to enrichment in iron or silica, which has competing effects on the velocity structure. This is a highly speculative model, but it can begin to reconcile the current observations of the deep mantle seismic structure with geochemical observations. An alternative to chemical layering is the presence of distinct blobs of chemically distinct mantle mixed into the lower mantle, in the so-called plum-pudding model (Davies, 1984). An intermediate scenario, motivated by recent seismic observations, of discrete piles of chemically distinct material in the LLSVP regions is discussed later.

Significant improvement of our understanding of the lower mantle will come with reliable determination of density heterogeneity directly from simultaneous inversion of normal modes and gravity observations. A first step in this direction has been presented by Ishii and Tromp (1999). While preliminary, that study found that high-density material may be piled up in the regions of low shear velocity, presumably hot material beneath the Pacific and Africa. A significant chemical heterogeneity density effect is needed to offset any thermal buoyancy of the upwellings. Until the models improve, it may thus be premature to associate the low shear velocities with upwellings, for chemical heterogeneity is likely to be important in the deep mantle.

The existence of large-scale lower mantle features enables the formulation of simultaneous or iterative inversions for dynamic features such as the geoid and dynamic topography, and this has emerged as a new area of research (e.g., Dziewonski et al., 1993; Forte and Mitrovica, 2001; Forte et al., 1993, 1994; Hager and Clayton, 1989; Hager et al., 1985; Mitrovica and Forte, 2004; Phipps Morgan and Shearer, 1993; Simmons et al., 2009, 2010; Soldati et al., 2012; Tackley, 2012). The primary additional parameter that is constrained in such geodynamic models is the viscosity structure, and it is generally found in geoid inversions and contemporary studies of glacial rebound processes that the viscosity of the lower mantle is one to two orders of magnitude higher on average than that of the average upper mantle (e.g., Mitrovica and Forte, 1997, 2004). This may be a consequence of lower mantle mineralogy, or it may represent the effect of devolatilization of the lower mantle during extensive melting early in Earth history. The simultaneous interpretation of thermal, chemical, and dynamic structures based on probabilistic tomographic velocity structures has been expanded to statistical approaches that recognize the uncertainties and correlations among thermal and compositional parameters (e.g., Cobden et al., 2009, 2012; Deschamps and Tackley, 2008; Deschamps and Trampert, 2003; Hernlund and Houser, 2008; Mosca et al., 2012; Trampert et al., 2004).

Resolving small-scale structures in the lower mantle by seismic imaging is a complementary approach to imaging the dynamic system. Essentially, seismologists look for the strong patterns expected to accompany mantle convection that is extensively driven by boundary layer flow. The primary elements of this are expected to be cold, sinking lithospheric slabs, which should have relatively high seismic velocities and tabular geometries, and hot, rising thermal plumes, which should have relatively low seismic velocities and cylindrical geometries. Extensive work has addressed lower mantle penetration by subducting oceanic lithosphere, which clearly penetrates down through at least the transition zone in some regions, given the occurrence of deep earthquakes in subduction zones. Jordan (1977) introduced a residual sphere modeling formalism for seeking patterns in travel time residuals from individual earthquakes in subduction zones, which was further developed by Creager and Jordan (1984, 1986a). These studies demonstrated the sensitivity of the method to both upper mantle and transition zone slab geometry and velocity heterogeneity, as well as to geometry of any steeply dipping slab extension into the lower mantle. Provocative results based on both P-wave modeling and S-wave modeling suggested that slab penetration to depths of at least 1000 km with little distortion other than steepening dip occurs in the Kuril, Marianas, and Japan arcs.

Additional applications of the residual sphere method were presented by Fischer et al. (1988, 1991), Zhou and Anderson (1989), Zhou et al. (1990), Boyd and Creager (1991), Ding and Grand (1994), and Pankow and Lay (1999). The method makes very explicit the limitations of arrival time data, as event location effects have a major effect on relative arrival time anomalies if the data coverage is limited (particularly true if

only teleseismic observations are used). As noted previously, tomographic methods are strongly biased by this unless the data coverage is such that residual patterns faithfully preserve the slab effects (which may be true when extensive upgoing and downgoing data are included, but not otherwise). Residual sphere modeling also makes clear the importance of deep mantle and receiver corrections, and early applications did not adequately address this issue. In fact, it has been shown that for S waves, much of what was initially attributed to near-source effects is eliminated when improved path corrections are applied (e.g., Deal and Nolet, 1999; Deal et al., 1999; Gaherty et al., 1991; Pankow and Lay, 1999; Schwartz et al., 1991). As global tomographic models improve further, this will become less of a problem. The analysis of differential residual spheres for events in the same slab, as first introduced by Toksöz et al. (1971), is one approach that has been pursued to suppress distant effects rather completely (e.g., Ding and Grand, 1994; Okano and Suetsugu, 1992; Pankow and Lay, 1999; Takei and Suetsugu, 1989). These studies indicate that in some cases, slabs may penetrate to depths of 800 km or more, but significant slab broadening may occur, as well as the reduction of velocity heterogeneity to on the order of 2%, much weaker than in early residual sphere studies and similar to the weak heterogeneity inferred when a priori slab structures are introduced into tomographic modeling. As regional and global tomography has advanced, there is a clear convergence with the results from the enhanced residual sphere modeling, with support for a few slabs directly penetrating into the lower mantle beneath Java and the Caribbean, but others such as the Izu and Japan slabs show strong deflections into large transition zone accumulations of slab material.

The analysis of upwelling regions is even more challenging, in that seismological imaging of low-velocity features is intrinsically difficult due to wave diffraction and wave front healing effects. Nonetheless, global tomography studies suggest that there are concentrated low-velocity regions beneath some of the major surface hot spots (e.g., Montelli et al., 2004; Schmerr et al., 2010; Sun et al., 2010; Takeuchi, 2009; Zhao, 2004), but the confidence in such features remains limited because the results appear to depend heavily on how inversions are parameterized and damped. While the evidence for lithospheric slab penetration into the upper portion of the lower mantle is relatively strong, the direct imaging of any plume upwellings remains in an early stage. Waveform healing effects and the intrinsic limitations of tomographic resolution for low-velocity regions require the evaluation of how tomography filters and smooths the images of specific deep mantle structures such as plumes (e.g., Boschi et al., 2007, 2008; Bull et al., 2009; Hwang et al., 2011; Ritsema et al., 2007; Styles et al., 2011). The complex structures near the base of the mantle that are described later include features attributed to plumelike instabilities from the thermochemical boundary layer above the CMB, but whether these features ascend to the surface or induce localized upwellings that do remains to be established.

1.22.4 D″ Region

The numerous efforts to image the detailed velocity structure below regions of subduction have been motivated as a test of the hypothesis of stratified versus whole-mantle convection, a key issue in mantle dynamics. Similarly, studying the structure of the D″ region is largely motivated by the notion that this region may play a critical role in mantle convection, especially if there is significant heating from below (e.g., Garnero et al., 2007a; Lay and Garnero, 2004). While most estimates of Earth's heat flow budget suggest that only 10–30% of the mantle's heat fluxes upward through the CMB (Lay et al., 2008; Zhong, 2006), this is still substantial heating that will give rise to a thermal boundary layer. Internal heating, resulting from radiogenic materials distributed in the mantle, is expected to contribute to large-scale flow without producing concentrated structures. In contrast, boundary layer-driven flow is expected to yield both localized upwellings and downwellings, which provide specific targets for seismic imaging. D″ structure is thus of particular interest as this region serves as the lower boundary layer of the mantle convection system. It is now generally appreciated that the lowermost mantle is also of great importance to convection in the core and the resulting geodynamo (e.g., Glatzmaier et al., 1999; Takahashi et al., 2008; Willis et al., 2007). The structure of D″ appears to be very complex, and efforts to elucidate this complexity underlie many approaches to understanding core and mantle dynamics.

1.22.4.1 Large-Scale Seismic Velocity Attributes

There are several important seismological probes of the large-scale elastic velocity structure in the D″ region. The large seismic velocity reductions across the CMB cause seismic wave energy to diffract into the geometric shadow zone at distances $>100^{\circ}$. Waves diffracted along the CMB are sensitive to the absolute velocities and the velocity gradients in the D″ region and have long been studied to constrain average and laterally varying structure (e.g., Alexander and Phinney, 1966; Bolt et al., 1970; Doornbos and Mondt, 1979; Mondt, 1977; Mula and Müller, 1980; Sacks, 1966; To and Romanowicz, 2009; To et al., 2011; Valenzuela and Wysession, 1998; Wysession, 1996; Wysession and Okal, 1989). These studies demonstrate that no single velocity structure sufficiently characterizes D″ everywhere and that in some cases, there are strong negative velocity gradients in D″, while in other places, there are near-zero or positive velocity gradients. There are also changes in the relative perturbation of P-wave and S-wave velocities that are likely due to mineralogical or textural origin (e.g., Wysession et al., 1999). Diffracted phases involve extensive lateral averaging of what appears to be a region rich in small-scale structure and therefore yield limited resolution, but they do provide important input into large-scale tomographic models for D″ because of their extensive spatial coverage (e.g., Bréger and Romanowicz, 1998; Castle et al., 2000; Kuo and Wu, 1997; Kuo et al., 2000).

The large-scale variations in D″ imaged by early global seismic wave travel time tomography studies were shown to have predominant degrees 2 and 3 spherical harmonic components (e.g., Dziewonski et al., 1996; Kuo and Wu, 1997; Kuo et al., 2000; Li and Romanowicz, 1996; Liu and Dziewonski, 1998; Masters et al., 1996; Su et al., 1994). These models established the presence of high shear velocities in D″ beneath the Pacific Ocean margins and low velocities beneath the central Pacific and the southeastern Atlantic and southern Africa

(Figure 4). This geometry results in a correlation between areas of slab subduction over the past several hundred million years (e.g., Lithgow-Bertelloni and Richards, 1998) and high-velocity regions of D″, which could result if slabs penetrate to the base of the mantle while retaining enough thermal anomaly to produce high seismic velocities. Similarly, the low-velocity regions of D″ are generally located below regions with hot spots at the surface, suggesting that D″ upwellings may penetrate all the way to Earth's surface.

1.22.4.2 Thermal Boundary Layer Aspect

To first order, the lower mantle appears to be a relatively uniform layer with properties varying radially largely due to self-compression and having most lateral heterogeneity concentrated in the D″ region above the CMB. The latter is consistent with the presence of a thermal boundary layer, as expected to result from heat fluxing out of the core into the mantle. The existence of a thermal boundary layer is strongly supported by the calculations of energetics of the geodynamo, which suggest that there must be some net flux of heat out of the core to sustain the core convective regime. The precise amount of heat flux is uncertain, with estimates ranging from 0.5 to 10 TW, and this amount must be added to heat conducted down the core adiabat (at least 2–5 TW) (e.g., Buffett, 2003). Thus, at least several TWs, and possibly as much as 15 TW of heat, are fluxing into the base of the mantle (about 44 TW flux through Earth's surface) (e.g., Kellogg et al., 1999; Lay et al., 2008; Zhong, 2006).

The CMB is a major compositional boundary; therefore, the heat flux from the core must conduct into the base of D″ with a superadiabatic temperature gradient (e.g., Stacey and Loper, 1983). Such a thermal boundary layer is likely to thicken over time and to build up instabilities that give rise to thermal plumes that carry excess temperatures from the boundary layer upward (e.g., Leng and Zhong, 2008, 2009). Time-dependent flow and uncertainty in material properties make dynamic calculations of CMB heat flux carried by thermal plumes very uncertain, but these probably provide a lower-bound estimate of total heat flux across the CMB (e.g., Glisovic et al., 2012; Manthilake et al., 2011; Mittelstaedt and Tackley, 2006; Monnereau and Yuen, 2010; Nakagawa and Tackley, 2008).

The very low viscosity of the core-side alloy ensures that the CMB is maintained at nearly isothermal conditions, temperature estimates of the CMB being in the range 2700–4200 °C (e.g., Williams, 1998). If there is no thermal boundary layer in the transition zone or mid-mantle, the overall temperature drop across the CMB thermal boundary layer must be on the order of 1000 ± 500 °C, comparable to that across the lithosphere. Lateral variations in temperature in the deep mantle will produce varying thermal gradients above the CMB resulting in a variable heat flux boundary condition on the core. In places where the mantle temperatures are relatively low, the heat flux will be higher than in places where the mantle temperature is relatively high. This heat flux variation is likely to exert a long-term influence of the mantle on the outer core convective regime (Buffett, 2003; Glatzmaier et al., 1999; Gubbins et al., 2007; Lay et al., 2004b; Sumita and Olson, 2000) and may influence the inner core as well (Sreenivasan and Gubbins, 2011).

The thickness of the boundary layer is quite uncertain due to significant pressure effects on material properties and questions about the existence of partial melting and chemical heterogeneity, but the general expectation is that the boundary layer may be as much as a few hundred kilometers thick (thicker than the lithospheric thermal boundary layer) mainly due to pressure effects suppressing the thermal expansion coefficient near the base of the mantle. In this case, the D″ region corresponds, at a minimum, to a thermal boundary layer with a rapid increase in temperature with depth. This is likely to be manifested as a reduction of seismic velocity gradients relative to the mid-mantle, given the inverse dependence of velocity on temperature. This may be a subtle effect in general due to the pressure effects on thermal expansion, but if the temperature increase approaches the eutectic melting point of the lower mantle or of some minor component in D″, very strong velocity reductions can occur for minor degrees of partial melting. The accurate determination of the velocity gradient above the CMB could thus potentially be used to constrain the thermal boundary layer properties (e.g., Doornbos et al., 1986; Lay and Helmberger, 1983a; Loper and Lay, 1995; Stacey and Loper, 1983), but this approach encounters the immediate challenge that the velocity gradient appears to vary laterally.

Like Earth's lithosphere, the thermal boundary layer at the base of the mantle is likely undergoing strong lateral and vertical flow, as upwellings produced by thermal boundary layer instabilities drain hot material from the boundary layer and downwellings replace it with cooler material. However, as a hot, low-viscosity boundary layer, there is probably much more small-scale structure in the D″ dynamic regime than is found in the cold, relatively stiff lithosphere. It is generally accepted that thermal heterogeneity within the boundary layer is partially responsible for the seismic inhomogeneity detected by Bullen (1949), and it likely contributes to the complexities described here, but it appears that more than just thermal heterogeneity is present.

As is true near Earth's surface, one cannot immediately attribute all variations in seismic velocities to the effects of temperature variations; chemistry may play an important or even the major part, especially given the inhibiting effects of great pressure on temperature derivatives for seismic velocities. The juxtaposition of the lowermost mantle boundary layer adjacent to the largest density contrast in Earth heightens the probability that there is also chemical heterogeneity in the D″ region. This may involve density-stratified residue from Earth's core formation process, ongoing chemical differentiation of the mantle, or even chemical reactions between the core and the mantle (e.g., Garnero and McNamara, 2008; Goarant et al., 1992; Hayden and Watson, 2007; Jeanloz, 1993; Knittle and Jeanloz, 1989; Lay, 1989; Manga and Jeanloz, 1996). The probability of both thermal and chemical heterogeneities existing within the lowermost mantle prompts the consideration of the region as a thermochemical boundary layer (e.g., Anderson, 1991; Lay, 1989; Lay et al., 2004b; Trønnes, 2009), much as Earth's lithosphere must be considered a thermochemical boundary layer due to large-scale chemical variations between oceanic and continental regions. The evidence for a thermochemical boundary layer is provided by several seismological attributes of the D″ region, as described in the next few sections.

1.22.5 D″ Discontinuities

Detailed studies of teleseismic waveforms indicate that P-wave and S-wave velocity structures both have a 0.5–3.0% velocity discontinuity at many locations near the top of the D″ region (the top of D″ is not precisely defined, and many researchers take it to correspond to either the depth at which there is a discontinuity or the onset of a change in velocity gradient, somewhere in the range from 50 to 350 km above the CMB). This feature is often called the D″ discontinuity (e.g., Wysession et al., 1998), and representative shear velocity structures obtained by waveform modeling are shown in Figure 6. These models, obtained for distinct regions of D″, involve a 2.5–3% shear velocity increase at depths from 130 to 300+ km above the CMB that is laterally extensive over intermediate-scale (500–1000 km) regions. Wysession et al. (1998) reviewed the many early studies of this structure, noting that there are substantial inferred variations in depth of the velocity discontinuity. Typically, S-wave velocity increases are larger than P-wave velocity increases, with the latter usually being 0.5–1.0%, though some models do propose 3% discontinuities (e.g., Weber and Davis, 1990; Wright et al., 1985). The increase in velocity at the top of D″ may be distributed over up to 30–50 km in depth, or it may be very sharp (e.g., Lay, 2008; Lay and Helmberger, 1983a; Lay and Young, 1989; Young and Lay, 1987a).

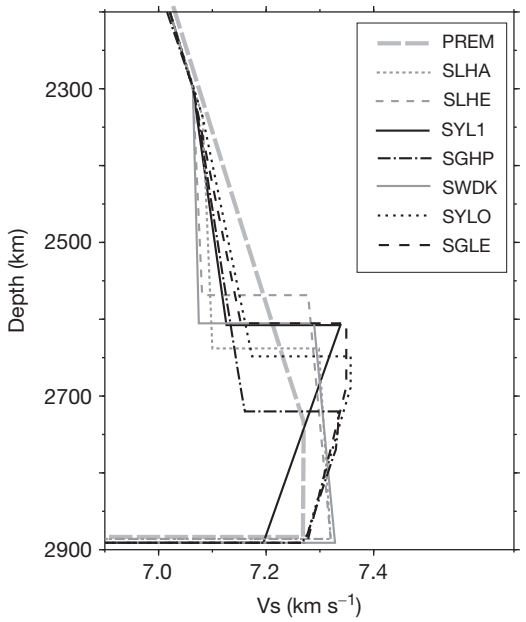

Figure 6 Radial profiles of S-wave velocity in the lowermost mantle: PREM (Dziewonski and Anderson, 1981), SLHE, SLHA (Lay and Helmberger, 1983a), SYL1 (Young and Lay, 1987a), SGHP (Garnero et al., 1988), SWDK (Weber and Davis, 1990), SYLO (Young and Lay, 1990), and SGLE (Gaherty and Lay, 1992). The discontinuity models represent localized structures, determined for spatially limited regions of the D″ layer, the locations of which are indicated in Figure 6.8(a). Shear velocity increases of 2.5–3.0% are found in regions under Eurasia (SWDK and SGLE), Alaska (SYLO), Central America (SLHA), the Indian Ocean (SYL1), and the central Pacific (SGHP). The velocity increase is typically modeled as a sharp discontinuity, but it may be distributed over up to 50 km in depth. Decreased velocity gradients above the discontinuity may exist but are artifacts of the modeling in most cases. The reduction of velocity below the discontinuity in more recent models (orange) may be real but may be an artifact of modeling a heterogeneous region with a one-dimensional model. The variations in depth of the discontinuity are uncertain due to the lack of constraint on velocity above and below the discontinuity, but some variation appears to exist.

1.22.5.1 Seismic Wave Triplications

The velocity increases at the top of D″ are primarily detected by reflections and triplications, which arrive ahead of the core-reflected PcP and ScS phases (e.g., Avants et al., 2006b; Chaloner et al., 2009; Ding and Helmberger, 1997; Gaherty and Lay, 1992; Houard and Nataf, 1993; Hutko et al., 2008, 2009; Kendall and Nangini, 1996; Kendall and Shearer, 1994; Kito and Krüger, 2001; Kito et al., 2004, 2007a,b; Kohler et al., 1997; Lay and Helmberger, 1983a; Lay et al., 2004a, 2006; Reasoner and Revenaugh, 1999; Sun and Helmberger, 2008; Sun et al., 2006, 2009; Takeuchi and Obara, 2010; Thomas and Weber, 1997; Thomas et al., 2002, 2004a,b; Thorne et al., 2007; Weber, 1993; Weber and Davis, 1990; Wright and Lyons, 1975; Wright et al., 1985; Young and Lay, 1987a, 1990). The clearest observations of deep mantle triplications are from distances of 65° to 95°, where the critical angle interaction with the velocity increase greatly enhances the amplitudes of the reflected signals relative to precritical distance ranges. Examples of the triplication arrival are shown in Figure 7, with broadband shear-wave data having a strong arrival between S and ScS phases that would not be predicted by a smooth velocity model such as PREM. The reflector that produces this extra arrival varies globally in depth by several

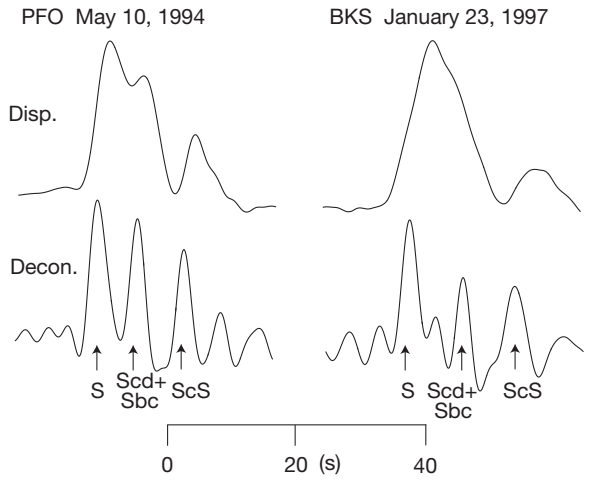

Figure 7 Examples of broadband SH displacements at stations PFO ($\Delta = 79.8°$) and BKS ($\Delta = 79.8°$) for two deep South American events. Instrument-corrected ground displacements (disp.) are shown in the top row. The first arrival is S, and about 15–20 s later, ScS, the reflection from the core–mantle boundary, arrives. Deconvolution by the event-averaged source wavelets and low-pass filtering below 0.3 Hz yields the spike trains below for each record (decon.). The intermediate arrival, Scd + Sbc (SdS), which is produced by triplication from a deep mantle velocity increase, is clearly isolated in the deconvolutions. Reproduced from Lay T, Garnero EJ, and Russell S (2004a) Lateral variation of the D″ discontinuity beneath the Cocos Plate. *Geophysical Research Letters* 31: L15612, http://dx.doi.org/10.1029/2004GL020300.

hundred kilometers (e.g., Kendall and Shearer, 1994) and appears to have regional-scale lateral variations of on the order of a hundred kilometers that may produce scattering rather than simple reflections (e.g., Emery et al., 1999; Freybourger et al., 1999; Hutko et al., 2006; Krüger et al., 1995; Lay et al., 1997, 2004a; Scherbaum et al., 1997; Thomas et al., 2004a,b; van der Hilst et al., 2007; Weber, 1993; Yamada and Nakanishi, 1998).

It has been argued that the D″ discontinuities are actually globally extensive, with lateral variations in depth and strength being the result of lateral temperature variations and interactions with upwelling and downwelling flow (e.g., Nataf and Houard, 1993; Sidorin et al., 1998, 1999). Many studies suggest that no reflections from a discontinuity are observed for certain regions (e.g., Wysession et al., 1998), but most of these fail to establish whether the data truly preclude the presence of some velocity increase. Others studies have questioned whether thee is a first-order discontinuity at all, preferring the notion that the extra seismic arrivals involve scattering from velocity gradients imaged in long-wavelength tomography models (e.g., Cormier, 1985; Haddon and Buchbinder, 1986; Liu et al., 1998; Schlittenhardt et al., 1985). The latter possibility requires large increases in the magnitude of the tomographic heterogeneities and/or sharpening of the velocity gradients, but there must be some relationship between the volumetric structure and the discontinuities (Ni et al., 2000). It has been demonstrated that scattering of SV energy into SH (Cormier, 1985) is not a likely explanation for the extra phases interpreted as triplication arrivals (Lay and Young, 1986). Young and Lay (1987b) showed that velocity decreases, as proposed by Haddon and Buchbinder (1986), cannot explain the data either. Thin high-velocity or low-velocity lamella models appear to fit some P-wave observations at least as well as first-order velocity discontinuity models (Freybourger et al., 1999; Thomas et al., 1998; Weber, 1994), but this has not been demonstrated convincingly for S-wave observations. An alternative is a transition in the heterogeneity spectrum with depth, possibly linking a gradient in anisotropy to the reflector (e.g., Cormier, 2000; Lay et al., 2004b).

One recent approach to determining the structure in the lowermost mantle with few assumptions about the nature of the structural complexity is waveform inversion, which uses large data sets and a complete calculation of waveform partial derivatives to structure for a set of basis functions. This approach has been applied to several areas where there had been previous forward modeling studies, allowing comparison of inferred structures. Applications have abounded (e.g., Fuji et al., 2010; He et al., 2010; Kawai and Geller, 2010b,c; Kawai et al., 2007a,b, 2009, 2010; Konishi et al., 2009, 2012). In general, there is fairly good agreement between forward modeling and waveform inversion studies for specific regions (Lay and Garnero, 2011), but it is clear that the resolution of velocity gradients and even depths of velocity increases and decreases is quite limited; details of all models, whether from forward modeling or inversion, must be interpreted with caution.

The regions with the strongest evidence for a shear-wave velocity discontinuity or strong velocity increase near the top of D″ are highlighted in **Figure 8(a)**. Wysession et al. (1998) showed individual data sampling in greater detail. Some of these areas also have evidence for a P-wave velocity discontinuity, but in some regions, such as under Alaska and Central America, any P-wave velocity discontinuity must be at or below the detection threshold of about 0.5% (Ding and Helmberger, 1997; Hutko et al., 2009; Reasoner and Revenaugh, 1999;

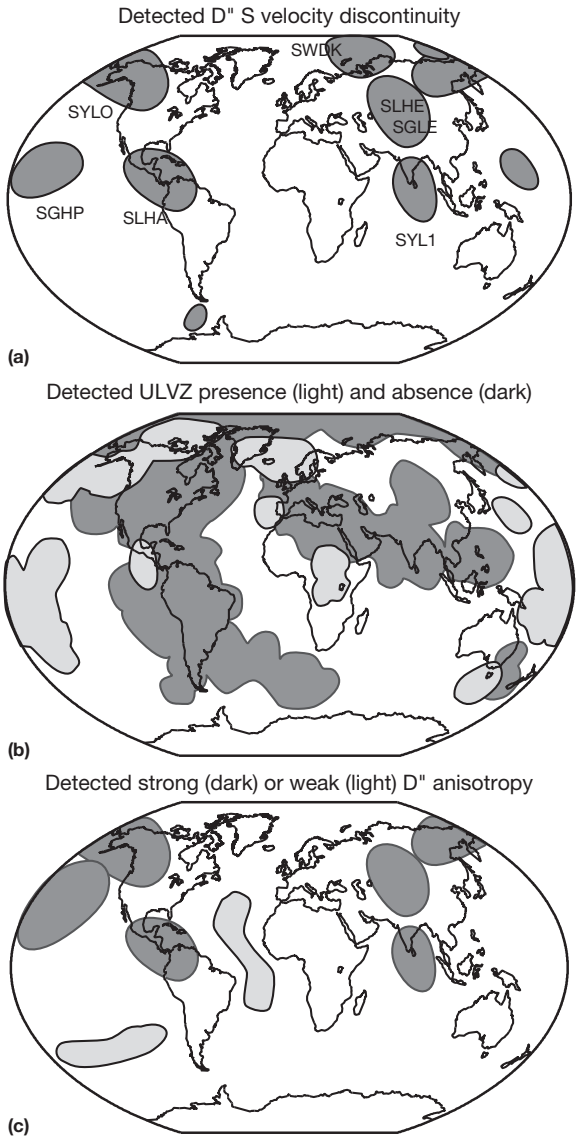

Figure 8 Maps summarizing spatial variations of seismic wave characteristics of D″. (a) Regions where regional shear velocity discontinuities have been observed in large numbers of data, typically with 2–3% increase in velocity at depths from 200 to 300 km above the CMB (see labeled models in **Figure 6**). (b) Regions where ULVZ structures at the CMB have been detected or not, primarily based on SPdiffKS observations and assuming a Fresnel zone appropriate for a horizontal layer. (c) Regions where regional studies of D″ shear-wave splitting have been conducted. Most areas exhibiting splitting have waveforms compatible with vertical transverse isotropy, with decoupling (or only weak coupling) of the transverse and longitudinal components of the S-wavefield, with 1–2% faster transverse components. Modified from Lay T, Garnero EJ, and Williams Q (2004b) Partial melting in a thermo-chemical boundary layer at the base of the mantle. *Physics of the Earth and Planetary Interiors* 146: 441–467.

Wright and Kuo, 2007; Young and Lay, 1989). Beneath Central America, there may be a small P-wave velocity reduction at the same depth as the S-wave velocity increase (Hutko et al., 2008). Stacking of array data is essential to detect such small discontinuities, and many 'non-observations' reported for individual seismograms must be viewed as inconclusive.

It is unlikely that long-period waveform inversion approaches will resolve the fine-scale structure reliably, so imaging methods will continue to play a major role in unveiling the structure. Several efforts have been made to apply industry-style migration methods to large data sets to image small-scale structures near the base of the mantle. Migrations of P-wave and S-wave data sets reveal both large-scale reflectors and localized, intermittent reflectors, with either velocity increases or decreases (e.g., Chambers and Woodhouse, 2006a,b; Hutko et al., 2006; Kito et al., 2007a,b; Ma et al., 2007; Rost and Thomas, 2010; van der Hilst et al., 2007; Wang et al., 2006, 2008). The complexity of structure in the deep mantle is approaching that of the lithosphere, and high-resolution imaging methods will be essential for making further progress.

The S-wave observations tend to be longer wavelength than the P-wave data used to look for the discontinuity, so it is viable that a transition zone several tens of kilometers thick may explain the absence of high-frequency precritical P-wave reflections. Most areas with strong evidence for an S-wave reflector are in the high-velocity regions beneath the circum-Pacific; the primary exception is under the central Pacific, where a variable S-wave velocity discontinuity is observed in a region having large-scale low D″ shear velocities (e.g., Avants et al., 2006b; Garnero et al., 1988; Kawai and Geller, 2010a; Lay et al., 2006; Russell et al., 2001). As the tomographic resolution of large-scale structure improves, the existence of strong lateral heterogeneities within both circum-Pacific and central Pacific regions is being recognized (Bréger and Romanowicz, 1998; Bréger et al., 2001; Fisher et al., 2003; Hung et al., 2005; Sun et al., 2007a, 2009; Wysession et al., 2001), so the bimodal characterization of the discontinuity structure is overly simplified.

It remains important to determine whether there is any density increase in D″ accompanying the seismic velocity increases, as this could help to resolve whether a chemical change or phase change is involved, either of which could strongly affect the dynamics of the boundary layer (e.g., Hansen and Yuen, 1988; Kellogg, 1997; Montague et al., 1998; Sleep, 1988; Tackley, 1998). Unfortunately, wide-angle triplication observations have very limited sensitivity to density contrasts, so this is an exceedingly difficult attribute to resolve, and normal modes have limited resolution of any small, laterally varying density increases in the relatively thin D″ region (e.g., Koelemeijer et al., 2012).

1.22.5.2 Phase Change in Perovskite

As noted in **Section 1.22.1.2**, the predominant lower mantle mineral, magnesium silicate $(Mg,Fe)SiO_3$ perovskite, is stable over a huge domain of lower mantle conditions spanning a several thousand kilometer depth range. However, high-pressure experiments conducted in Japan (Murakami et al., 2004; Oganov and Ono, 2004) first demonstrated that for pressures greater than about 120 GPA, corresponding to depths in the lowermost mantle within a few hundred kilometers of the CMB, magnesium silicate perovskite at a temperature near 2500 K undergoes a transition to a new mineral structure, called postperovskite. This phase transition is widely viewed as the probable explanation for the D″ discontinuity, as it can plausibly account for salient features of the seismic observations (Bower et al., 2013; Hirose, 2006, 2007; Lay and Garnero, 2007; Lay et al., 2005; Shim, 2008).

The phase transition from perovskite to postperovskite does not involve a change of mineral composition, but the postperovskite phase is about 1–1.2% denser and has higher shear modulus than perovskite. X-ray diffraction studies of experimental samples at high pressures established the existence and the change in volume of the postperovskite phase and provided constraints on the atomic lattice for theoretical modeling of the precise crystal structure of the mineral (Caracas and Cohen, 2006; Iitaka et al., 2004; Komabayashi et al., 2008; Martin and Parise, 2008; Murakami et al., 2004, 2005; Oganov and Ono, 2004; Ono and Oganov, 2005; Stackhouse et al., 2005b; Tsuchiya et al., 2004a; Wentzcovitch et al., 2006). Molecular dynamics modeling is required to predict the crystal structure of the postperovskite phase, and the theoretical calculations provide many important physical characteristics of postperovskite. This includes the prediction of the slope of the phase boundary in pressure–temperature (P–T) space, called the Clapeyron slope. The computed Clapeyron slope for the pure Mg end-member composition, $MgSiO_3$, is about 7.5 MPa K^{-1}, a rather large positive value typical of the postperovskite structure (Hirose and Fujita, 2005; Tsuchiya et al., 2004a). Experiments suggest the slope may be as large as 11.5 MPa K^{-1} (Hirose et al., 2006; Tateno et al., 2009). The positive value indicates that the phase boundary should occur at lower pressure (shallower in the mantle) in regions that are relatively lower temperature. Large variations in the depth of the phase transition could thus result from the strong thermal heterogeneity expected to exist in the vicinity of the thermal boundary layer in the lowermost mantle (Lay et al., 2005). Experiments also indicate high electrical conductivity for postperovskite, which may enhance electromagnetic coupling across the CMB (Ohta et al., 2008b), and it has been explored whether this is detectable (Velimsky et al., 2012).

Numerical calculations (e.g., Stackhouse and Brodholt, 2007; Tsuchiya and Tsuchiya, 2006; Tsuchiya et al., 2004b) and recent laboratory experiments (e.g., Guignot et al., 2007; Murakami et al., 2007b) also predict the crystal elasticity of postperovskite for lower mantle P–T conditions, providing estimates of the seismic P-wave and S-wave velocities. The P-wave velocity changes little relative to that for perovskite as a result of competing effects of increasing shear modulus, increasing density, and decreasing bulk modulus (Wookey et al., 2005b); however, the S-wave velocity is about 0.5–2% faster than for perovskite. If the transition from perovskite to postperovskite is confirmed to occur over a small pressure (depth) range, the resulting rapid increase in S-wave velocity is expected to produce a velocity increase that can reflect shear-wave energy. This could account for the shear velocity discontinuities shown in **Figure 6** (e.g., Kawai and Tsuchiya, 2009; Lay and Garnero, 2007; Tsuchiya et al., 2004b; Wookey et al., 2005b). The theoretical models of elasticity also predict

anisotropic properties of the postperovskite crystals. These differ significantly from those for perovskite in low-temperature calculations, with increasing temperature reducing the differences but still allowing a contrast in anisotropic properties under deep mantle conditions (e.g., Merkel et al., 2006; Oganov et al., 2005; Stackhouse et al., 2005b).

Numerous studies have used stable low-pressure mineral forms such as $CaIrO_3$, $MnGeO_3$, $MgGeO_3$, $CdGeO_3$, and $CaRuO_3$ and $NaCoF_3$, $NaMgF_3$, and $NaNiF_3$ as analogs for characterizing the postperovskite transition and deformational properties under relatively accessible (for both laboratory and computations) P–T conditions (e.g., Boffa Ballaran et al., 2007; Cheng et al., 2010, 2011; Dobson et al., 2011; Hirose et al., 2005b, 2010; Hunt et al., 2009; Hustoft et al., 2008a,b; Ito et al., 2010; Kojitani et al., 2007a,b; Kubo et al., 2006, 2008; Martin et al., 2006a,b, 2007a,b; Metsue et al., 2009; Miyagi et al., 2008; Miyajima et al., 2006, 2010; Niwa et al., 2007, 2011, 2012; Runge et al., 2006; Shim et al., 2007; Stolen and Tronnes, 2007; Tateno et al., 2006, 2010; Tsuchiya and Tsuchiya, 2007; Umemoto et al., 2006; Usui et al., 2010; Walte et al., 2007; Wu et al., 2011).

The pioneering experimental and theoretical work on postperovskite was performed for the pure magnesium ($MgSiO_3$) end-member and its analogs, but effects of the presence of iron (Fe) and aluminum (Al) have now been extensively explored experimentally and theoretically (Akber-Knutson et al., 2005; Andrault et al., 2010; Caracas, 2010a; Caracas and Cohen, 2007, 2008; Catalli et al., 2010a; Grocholski et al., 2012; Hirose et al., 2008; Jackson et al., 2009; Lee et al., 2009; Mao et al., 2004, 2005, 2006a,b, 2007; Metsue and Tsuchiya, 2011; Nishio-Hamane and Yagi, 2009; Nishio-Hamane et al., 2007; Sakai et al., 2009b; Shieh et al., 2011; Shim et al., 2008, 2009; Sinmyo et al., 2006, 2008a,b, 2011; Spera et al., 2006; Stackhouse et al., 2005a, 2006a; Tateno et al., 2005, 2007; Tschauner et al., 2008; Tsuchiya and Tsuchiya, 2008; Yamanaka et al., 2012; Zhang and Ogonov, 2007; Zhang et al., 2012). It is believed that lower mantle silicates probably contain at least 10–15% iron substitution for magnesium. Initial work suggested that having iron in the postperovskite mineral should reduce the pressure of the phase transition, such that it may occur hundreds of kilometers shallower in the mantle than for an iron-free mineral (Mao et al., 2004). These results have been contested in experiments that find less pressure effect due to the inclusion of Fe (Hirose et al., 2006). Theoretical predictions of the effects of Al substitution for both Mg and Si in the crystal lattice suggest that there may be a significant depth range (a few hundred kilometers) over which perovskite and postperovskite can coexist, which would reduce any velocity discontinuity, weakening seismic wave reflections from the transition (e.g., Akber-Knutson et al., 2005; Andrault et al., 2010; Catalli et al., 2009; Tateno et al., 2005). The compositional variations complicate any connection between seismic models and specific phase change properties, and there may be kinetic effects on the deep mantle phase change that have to be accounted for as well.

Lower mantle rocks, like all rocks in the Earth, will involve an assemblage of mineral phases, with variations in crystal size and rock fabric as a result of solid-state convection. While there has been some experimental work done on real rock samples at lower mantle pressures and temperatures with the postperovskite phase being observed (Murakami et al., 2005; Shieh et al., 2006), full assessment of coexisting multiphases is still in an early stage. For example, the properties of ferropericlase (Mg,Fe)O are important, especially the partitioning coefficient of iron between perovskite and ferropericlase (e.g., Kobayashi et al., 2005; Nakajima et al., 2012). The Fe spin transitions may also influence the postperovskite phase boundary, with iron partitioning affecting the postperovskite composition (Caracas, 2010b; Hsu et al., 2012; Li, 2007; Lin et al., 2008; Mao et al., 2010; Sturhahn et al., 2005; Yamanaka et al., 2010; Yu et al., 2012).

Subducted oceanic slab material could be relatively low temperature compared to surrounding ambient mantle, and if it penetrates to the base of the mantle, it may thus preferentially undergo transition to postperovskite, resulting in a reflecting surface at the phase change within slab material, even if the boundaries of the slab are not strong reflectors. Postperovskite may exist in large patches of lower mantle material cooled by recently subducted slab material, and as this heats up over time, the material may change back to perovskite. If the pattern of heterogeneity in **Figure 4** indicates relative temperatures (rather than a compositional change), low-velocity regions should be hotter, and therefore, any postperovskite phase transition may occur at greater depth or not at all in the low-shear-velocity regions (Helmberger et al., 2005). Seismologists are seeking to establish whether the low-shear-velocity regions have any S-wave velocity discontinuity, but there is so far limited evidence for this other than under the central Pacific (e.g., Avants et al., 2006b; Lay et al., 2006; Russell et al., 2001), and that may be for a region near the margin of the low-shear-velocity province. It is interesting to note that while the volumetric shear velocity in the central Pacific is relatively low, the discontinuity, while highly variable, is not located much deeper than in circum-Pacific regions, contrary to the predicted thermal effect. Compositional effects may compete with thermal effects on the phase transition in this region (Ohta et al., 2008a).

The CMB is likely to be at a temperature too high for postperovskite to be stable, so there may be a thin basal layer with rapidly increasing temperature below regions cooled by slab material, in which the minerals transform back to perovskite (Hernlund et al., 2005; Lay et al., 2006; van der Hilst et al., 2007). A deeper velocity discontinuity with a velocity decrease should be present if this is the case, but this is seismically much more difficult to observe than a velocity increase because there is no critical angle amplification (Flores and Lay, 2005). Waveform stacking and detailed modeling are essential for the confident identification of any small velocity decreases in D″. Stacking of ScS data traversing the high-velocity region under the Cocos plate does not reveal any negative velocity discontinuity below the positive velocity increase at the top of D″, but similar stacking for data traversing the central Pacific does show a sharp decrease about 60 km above the CMB (Avants et al., 2006a,b; Lay et al., 2006). If paired velocity increases and decreases can be confidently identified, they present the opportunity to directly estimate the temperature gradient, under the assumption that the structure does involve double intersection of the phase boundary. Coupled with an assumption of thermal conductivity, one can then estimate heat flux directly (Lay et al., 2006; van der Hilst et al., 2007), although the detailed

nature of the phase boundary in the thermal gradient is important to consider (Buffett, 2007; Hernlund, 2010; Hernlund and Labrosse, 2007). The importance of thermal conductivity in D″ has prompted a substantial experimental and theoretical research effort, complicated by the difficulty of reliably measuring thermal conductivity at extreme *P*–*T* conditions, the uncertain mineralogy Fe spin state, and uncertain relative contribution from phonon and radiative conductivity (e.g., Chen et al., 2012b; Goncharov et al., 2006, 2008, 2009, 2010; Haigis et al., 2012; Hofmeister, 2008; Keppler et al., 2007, 2008; Ohta et al., 2012; Stackhouse et al., 2010).

The large positive Clapeyron slope of the postperovskite phase boundary in the presence of lateral temperature differences at the base of the convecting mantle may influence the generation of boundary layer instabilities. Warmer regions of the boundary layer will have a thinner layer of dense postperovskite mineralogy, while colder regions of the boundary layer will have a thicker layer of the denser material. This thermally induced topography on the phase boundary is like that near the 410 km olivine/wadsleyite phase transition, and in both cases, the pattern promotes flow of material across the boundary layer (as the elevated dense material sinks, it pulls down overlying material that transforms to the denser phase). Because the Clapeyron slope for the deep mantle transition is about twice that of the upper mantle transition, the effect is enhanced, and convection models that include the postperovskite transition have quite unstable lower thermal boundary layers that tend to generate vigorous deep mantle flow (e.g., Cizkova et al., 2010; Kameyama and Yuen, 2006; Matyska and Yuen, 2004, 2006; Monnereau and Yuen, 2007; Nakagawa and Tackley, 2004, 2005, 2006; Tackley et al., 2007; Tosi et al., 2010; van den Berg et al., 2010; Yuen et al., 2007). Seismological mapping of the phase boundary can thus provide a probe of the thermal and dynamic processes in the lowermost mantle.

There are indications that D″ material may be very weak and have low viscosity (e.g., Ammann et al., 2010; Nakada and Karato, 2012; Nakada et al., 2012) due to both the high-temperature boundary layer effect on viscosity and efficient diffusion within the minerals. Such a low-viscosity layer has significant effect on boundary layer deformation and instabilities that may even influence the geoid (e.g., Cadek and Fleitout, 2006; Nakagawa and Tackley, 2011; Samuel and Tosi, 2012; Tosi et al., 2009).

1.22.6 Large Low-Shear-Velocity Provinces

The two large regions of low shear velocity in the lowermost mantle located beneath the south-central Pacific and southern Africa/southern Atlantic/southern Indian Ocean regions (**Figure 4**) are particularly unusual structures. Their lateral extent is far greater than might be expected for a hot upwelling plume from a thermal boundary layer, giving rise to the label 'superplumes.' However, attaching dynamic attributes to these regions based on the sign of their velocity anomaly may be misleading. For example, the continents have comparably large-scale regions of relatively high-shear-velocity material in the lithosphere, and one could thus infer that they are cold, sinking regions, whereas the reality is that they are chemically buoyant. The deep mantle anomalies have much stronger S-wave velocity reductions than P-wave velocity reductions, which suggests that some chemical change may be involved. The uncertain thermochemical nature of these LLSVPs warrants a dynamically neutral name.

There are also smaller-scale regions with low seismic velocities in the lower mantle that may be consistent with plumes rising from the thermal boundary layer (e.g., Montelli et al., 2004; Zhao, 2004), and it remains to be determined whether these are distinct from the LLSVPs. For example, while the tomographic model of Ritsema et al. (1999) does not have a low-shear-velocity zone in the lower mantle beneath Iceland, Bijwaard and Spakman (1999) presented a P-wave velocity image with low velocity under Iceland all the way to the CMB, and Helmberger et al. (1998) found very low S-wave velocities in D″ beneath Iceland. Goes et al. (1999) found a low P-wave velocity structure beneath Europe from 660 to 2000 km depth, which they invoke as the source of small plumes in the upper mantle associated with volcanism in Europe. Smaller-scale plume or slab features that are below the current resolution of global seismic tomography, but can be resolved in regional-scale inversions (e.g., Hung et al., 2005; Wysession et al., 2001), exist in the D″ region as well. Innovative scattering analysis or array imaging may prove to be the only means by which to constrain even smaller-scale structures (e.g., Ji and Nataf, 1998; Tibuleac and Herrin, 1999; Tilmann et al., 1998). The characterization of LLSVPs is rapidly improving and more detailed than for any of the smaller-scale structures, so this section will focus on them.

1.22.6.1 Seismic Velocity Properties

The existence of the LLSVPs was first indicated by mantle shear-wave velocity tomography models (e.g., Dziewonski et al., 1993), and as discussed earlier, there is fairly good consistency among recent global models for the large-scale structure (e.g., Lekic et al., 2012). The global distribution of sources and permanent seismic stations limits the resolution of velocity gradients and total extent of the LLSVPs under Africa (**Figure 9**) and the Pacific, so deployments of portable instruments have been important for detailed differential travel time analyses and waveform modeling used to improve the resolution of LLSVP structure.

Ritsema et al. (1998b) and Ni and Helmberger (2003a,b) found that low-shear-velocity structure under southern Africa involves 3% anomalies and strong lateral gradients, both of which are more pronounced than in tomographic models. The LLSVP model they advance extends upward about 800–1200 km from the CMB, so the anomalous material is not confined to D″. Even stronger anomalies are reported in the D″ region below the southeastern Atlantic and southern Indian Ocean, with 1–10% S-wave velocity reductions increasing with depth across a 300 km thick layer (Wang and Wen, 2004, 2007a; Wen, 2001, 2006; Wen et al., 2001). Intermediate estimates of shear velocity reductions (1–7%) under the south Pacific LLSVP have been reported (e.g., Ford et al., 2006; Tanaka, 2002; To et al., 2005), and the margins and internal structure of the Pacific LLSVP have been constrained by He et al. (2006), Takeuchi et al. (2008), Tanaka et al.

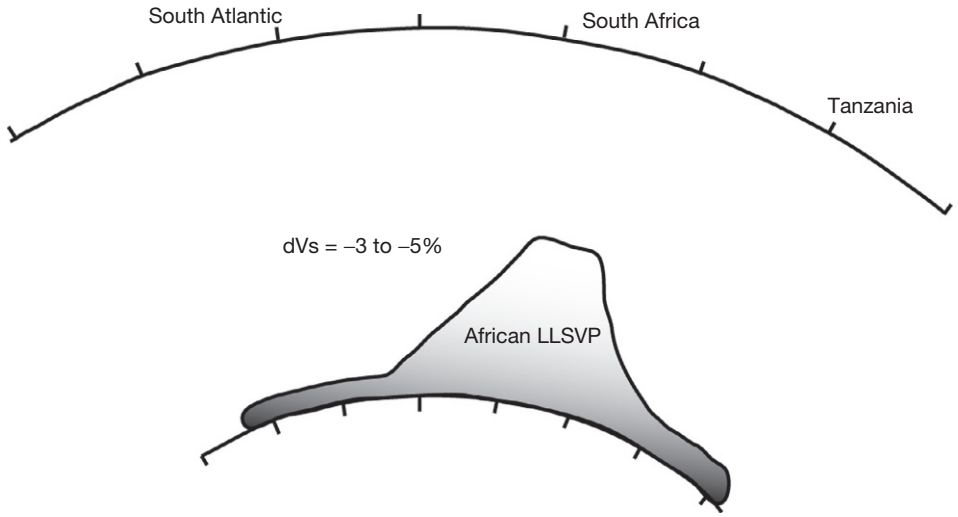

Figure 9 A cross section through the LLSVP beneath Africa and the southern Atlantic, indicating the region of anomalously low shear velocities. The tick marks are 10° increments along a great-circle arc trending from southwest (left) to northeast (right). The velocity anomaly is about −3% in the shallower part of the structure and may increase to about −5% in the D″ region. The geometry of the structure is constrained by S, ScS, and SKS raypaths from various azimuths recorded at mainly African stations. The structure has the appearance of an upswept pile that is about 4000 km wide at the base and extends 1300 km upward from the CMB. Modified from Wang Y and Wen L (2007a) Geometry and P and S velocity structures of the "African Anomaly." *Journal of Geophysical Research* 112: B05313, http://dx.doi.org/10.1029/2006JB004483.

(2009), To and Romanowicz (2009), He and Wen (2009, 2011, 2012), Koki et al. (2012), and Takeuchi (2012).

There are very strong lateral gradients in seismic velocity structure in D″ on the margins of the LLSVPs that seem incompatible with thermal variations alone, unless there is a superimposed chemical or melting effect (e.g., He and Wen, 2012; Ni et al., 2002, 2005; To et al., 2005; Wen et al., 2001). Even in the mid-mantle, the lateral gradients remain strong, which is difficult, if not impossible, to explain by simple thermal gradients (e.g., Ni et al., 2002). Given the reduction of the sensitivity of shear velocity to temperature at deep mantle pressures, lateral thermal changes of 500–1000° over ~100 km are needed to account for the observed velocity anomalies, which could lead to the onset of partial melting that can strongly reduce velocities (Lay et al., 2004b). But chemical variations appear to be important in LLSVPs, so the temperature contrasts may be far lower.

One of the key indications that LLSVPs involve chemical heterogeneity comes from comparisons of P-wave and S-wave velocities. Generally, global tomography models find good correlation between P-wave velocity and S-wave velocity structures in the lowermost mantle (e.g., Antolik et al., 2003; Houser et al., 2008; Masters et al., 2000); however, this correlation appears to break down in certain regions, such as beneath the northern Pacific, where P-wave velocity anomalies tend to be positive and S-wave velocity anomalies tend to be negative. A south-to-north decrease in the P-wave/S-wave velocity ratio has also been found using diffracted waves traversing D″ below the northern Pacific (Wysession et al., 1999). While the sampling of the lowermost mantle remains relatively poor for P waves (S-wave phases such as ScS and SKS greatly augment the deep mantle S-wave sampling), the LLSVPs do tend to have low-velocity expressions in global P-wave models. However, the relative strength of the anomalies is important to consider.

Shear velocity models show markedly stronger increases in RMS velocity heterogeneity in the lowermost 300 km of the mantle than do compressional velocity models, although the various models do differ in the extent to which shear velocity heterogeneity is concentrated toward the CMB (**Figure 5**). Even for well-correlated P-wave and S-wave velocity models (e.g., Houser et al., 2008; Masters et al., 2000), this raises the possibility of distinct behavior for P waves and S waves due to competing thermal and chemical variations, coupled with the possible presence of low degrees of partial melting (Lay et al., 2004b; Simmons and Grand, 2002). Indeed, the variability in velocity ratios and the occasional decorrelation of P-wave and S-wave anomalies provide strong evidence that thermal effects alone cannot explain all D″ seismic observations.

Simultaneous inversions of P-wave and S-wave data have been performed in attempts to isolate bulk sound velocity variations from shear velocity variations (e.g., Antolik et al., 2003; Houser et al., 2008; Kennett et al., 1998; Masters et al., 2000; Resovsky and Trampert, 2003; Robertson and Woodhouse, 1996; Su and Dziewonski, 1997; Trampert et al., 2004), but there are significant discrepancies between these models, perhaps as a consequence of incompatible resolution of P-wave and S-wave structures on a global basis. Della Mora et al. (2011) and Hernlund and Houser (2008) argued that resolution differences cannot account for the decorrelation overall. Direct comparisons of P-wave and S-wave travel time anomalies on specific paths support the possible decorrelation of these elastic velocities for localized regions within D″ (e.g., Lay et al., 2004b; Saltzer et al., 2001), as well as reaffirming the greater variations for S-wave velocities than P-wave velocities in LLSVPs (**Figure 10**; e.g., Simmons and Grand, 2002; Tkalcic and Romanowicz, 2002). The overall result is that LLSVPs have a bulk sound velocity anomaly that is anticorrelated with the S-wave velocity anomalies, and this dominates the pattern of

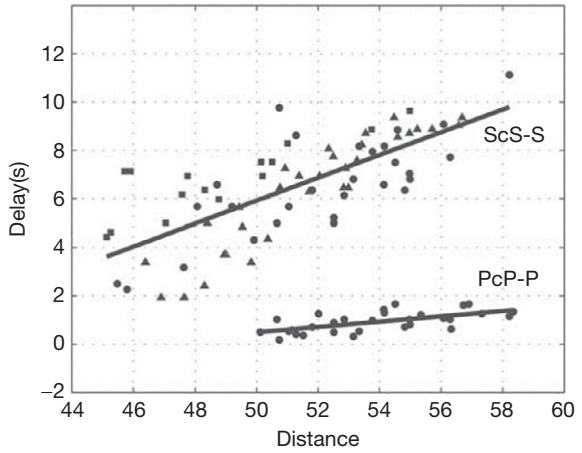

Figure 10 Differential travel times for ScS-S and PcP-P for paths sampling the southern margin of the African LLSVP. The S waves have much larger relative times, requiring shear velocity decreases 2–2.8 times stronger than the compressional velocity reductions depending on the depth extent of the anomalous region. This relative behavior is stronger than expected for a thermal variation in uniform lower mantle chemistry and requires either a compositional effect or a contribution from partial melting. Reproduced from Simmons NA and Grand SP (2002) Partial melting in the deepest mantle. *Geophysical Research Letters* 29, http://dx.doi.org/10.1029/2001GL013716.

the large-scale inversions for bulk sound velocity anomalies. This behavior requires an increase in incompressibility that contrasts with a decrease in rigidity in the LLSVPs. While this type of behavior is not necessarily unique to LLSVPs, it is generally accepted that at least part of (and possibly all of) their shear velocity anomaly is due to chemical anomaly, possibly involving enrichment in iron (Deschamps et al., 2011, 2012; Trampert et al., 2004). Some researchers have been reevaluating whether thermal effects alone dominate, using updated estimates of bulk chemistry and predicted elasticity, or whether the evidence for chemical heterogeneity in LLSVPs is truly compelling (e.g., Brodholt et al., 2007; Davies et al., 2012; Schuberth et al., 2009). This is clearly important to resolve.

There is also some indication that density heterogeneity exists at the base of the mantle based on the analysis of normal modes and that on a large scale, dominated by the two LLSVPs, it is anticorrelated with shear velocity (and, hence, positively correlated with bulk velocity models), favoring chemical heterogeneity (Ishii and Tromp, 1999; Trampert et al., 2004). Thus, LLSVPs may be denser than surrounding mantle and hence dynamically stabilized even if they are hotter than their surroundings, a situation inverse to that for continents. This remains a topic of much uncertainty (e.g., Kuo and Romanowicz, 2002; Romanowicz, 2001), and resolving the density structure is critical for assessing whether LLSVPs are buoyant or not.

1.22.6.2 Thermal–Chemical Interpretations

The very presence of the LLSVPs in the deep mantle at this stage of Earth evolution suggests that unless they are being replenished by some process, such as segregation of former oceanic crustal components, they are likely to be very long-lived and not particularly buoyant (e.g., Ni and Helmberger, 2003a). Their large vertical extent certainly could reflect some thermal buoyancy, perhaps in competition with chemical negative buoyancy, but the LLSVPs may also represent mounds of low-velocity chemical heterogeneities piled up under large-scale mantle upwellings (Garnero and McNamara, 2008; Garnero et al., 2007a; Maruyama et al., 2007; McNamara and Zhong, 2004, 2005). If the chemical anomaly in the LLSVP is primarily responsible for the sharp edges of these structures, which can be nearly vertical in the deep mantle, there are many ensuing implications. One is that it seems likely that LLSVPs will have thermal boundary layers developed along their discrete boundaries, with these boundary layers conducting heat out of (or into) the pile. If the LLSVPs are enriched in radiogenic materials, they may be relatively hot, and the enveloping thermal boundary layers might themselves become detached to rise as thermal plumes, perhaps entraining trace materials of the distinct chemistry of the LLSVP (Deschamps et al., 2012). The distinct material properties of LLSVPs associated with their chemistry (e.g., the relatively high incompressibility suggested by the Vp/Vs anomaly) have implications for the internal dynamics of the LLSVPs. High incompressibility can lead to a metastable condition for thermal upwellings that causes them to stall in the mid-mantle, producing the large mound of the LLSVP primarily by internal dynamics rather than external flow conditions (e.g., Sun et al., 2007b; Tan and Gurnis, 2005, 2007; Tan et al., 2011). Long-term oscillations of metastable plume may account for Pacific geoid anomalies (Cadio et al., 2011).

The general correlation of low-velocity regions in D″ with the surface distribution of hot spot volcanoes (e.g., Williams et al., 1998) has long been noted, but even stronger correlation is found between the margins of LLSVPs and hot spot volcanoes (Thorne et al., 2004), supporting the notion that boundary layer instabilities may shed from the edges of LLSVPs (Davaille, 1999; Jellinek and Manga, 2002), rather than the entire structure being a superplume. The present-day location of LLSVPs places their margins below many reconstructed locations of large igneous provinces produced over several hundred million years (e.g., Burke and Torsvik, 2004; Burke et al., 2008; Torsvik et al., 2006, 2008). This suggests the possibility of very long time stability of the thermochemical piles (Nebel et al., 2007) and their importance for generating boundary layer instabilities (e.g., Garnero et al., 2007a; Steinberger and Torsvik, 2012) that have affected Earth's surface profoundly throughout at least Cenozoic and Mesozoic time (Dziewonski et al., 2010). The notion that deep mantle heterogeneity, which displaces sluggishly relative to the upper mantle, may play a long-term role in surface geologic processes emphasizes the importance of resolving lower mantle structure and processes.

1.22.7 Ultralow-Velocity Zones

Another important aspect of D″ that has been inferred from seismic waveform investigations is the widespread existence of a layer from 5 to 40 km thick overlying the CMB with very strong P-wave and S-wave velocity reductions of up to −10% and −30%, respectively (see **Figure 8(b)**). Early observations of these ULVZs are summarized by Garnero et al. (1998) and Thorne and Garnero (2004). Extensive regions of ULVZ appear

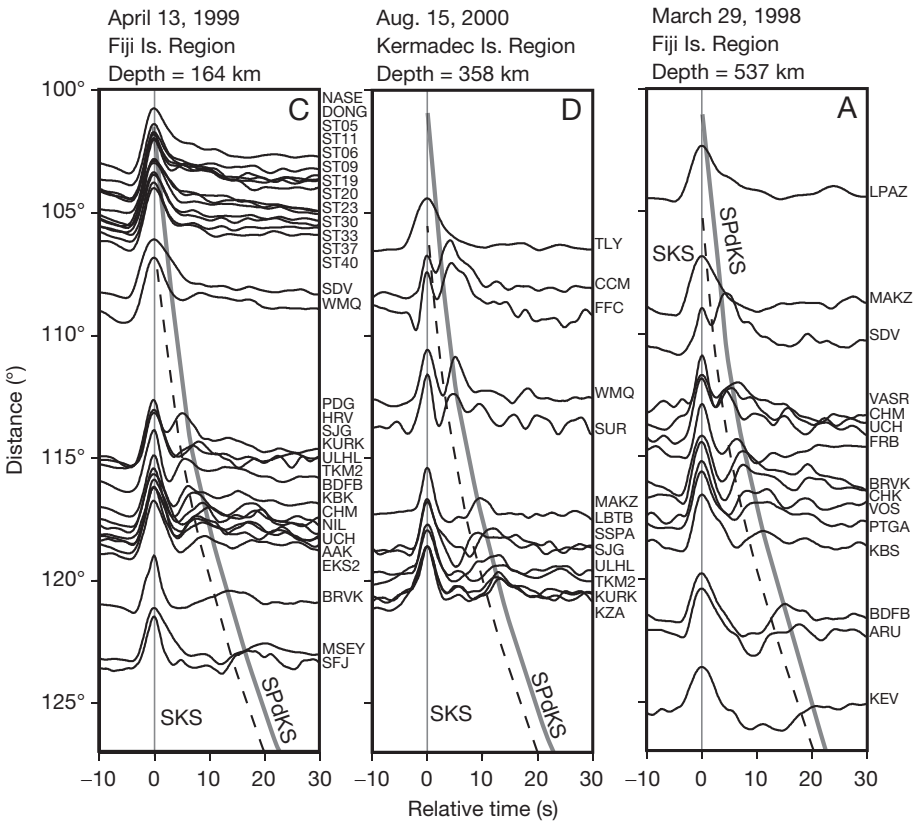

Figure 11 Waveforms with anomalously late SPdKS arrivals. The signals are aligned on SKS, with the dashed curves indicating the expected time for the peak of SPdKS based on the PREM structure. The observed arrivals are 2–3 s later than expected, which must be due to anomalously low P velocity right at the CMB where SPdKS diffracts along the boundary. Modeling indicates that about 5–10% low P velocity in a layer 5–10 km thick can match the data. This strong P velocity reduction defines the ULVZ. Courtesy of Ed Garnero.

to exist, although the actual lateral extent is uncertain because either broad horizontally stratified regions or localized three-dimensional domes and blobs may explain the data (Helmberger et al., 1998, 2000). In some cases, the ULVZ region appears to be enhanced to scales of 600–900 km lateral extent and several tens of kilometers of thickness, as under the central Pacific (Cottaar and Romanowicz, 2012) and below the region northeast of Tonga (Thorne et al., 2013). Similarly, the absence of seismically detectable ULVZ does not preclude the presence of a very thin (<5 km) layer that is not resolved by seismic probes of the CMB, and only upper bounds on thickness and velocity drop can be determined (Stutzmann et al., 2000). Nonetheless, there are regions where there is no evidence of complexity in structure right at the CMB in high-quality short-period data (e.g., Castle and van der Hilst, 2000; Persch et al., 2001) and other regions with evidence for rapid small-scale variations in ULVZ structure (e.g., Havens and Revenaugh, 2001; Rost and Revenaugh, 2003). Thus, there are certainly variations in ULVZ structure, so these structures are not globally represented by any one-dimensional model.

1.22.7.1 Seismic Phases Used for Detection

Evidence for a ULVZ at the base of the mantle was first presented by Garnero et al. (1993) and Silver and Bina (1993) based on the behavior of SKS phases that interact with the CMB. The primary evidence for the ULVZ involves delayed $SP_{diff}KS$ phases (**Figure 11**; e.g., Garnero and Helmberger, 1995, 1998; Helmberger et al., 1998; Rondenay and Fischer, 2003; Rondenay et al., 2010; Thorne et al., 2013), precursors to PcP reflections (e.g., Mori and Helmberger, 1995; Revenaugh and Meyer, 1997; Ross et al., 2004; Rost et al., 2006, 2010b), precursors to ScS reflections (**Figure 12**; Avants et al., 2006a), S-wave diffractions (Cottaar and Romanowicz, 2012; To et al., 2011), precursors/postcursors to ScP reflections (Garnero and Vidale, 1999; Idehara, 2011; Idehara et al., 2007; Reasoner and Revenaugh, 2000; Rost and Revenaugh, 2001, 2003; Rost et al., 2005, 2006, 2010a), and SKKS/SKS ratios (Zhang et al., 2009). Strong scattering of PKP and PKKP precursors has also been used to constrain ULVZ structure at the CMB (Rost and Garnero, 2006; Vidale and Hedlin, 1998; Wen, 2000; Wen and Helmberger, 1998; Xu and Koper, 2009; Zou et al., 2007). A variety of seismic wave probes of ULVZ structure are needed in order to characterize the P-wave, S-wave, and density structures, as each phase has sensitivity to more than one parameter. For some phases, there are strong trade-offs with structure on the core side of the CMB as well, with a thin layer of finite rigidity in the outermost core being an alternate possibility (e.g., Buffett et al., 2000; Garnero and Jeanloz, 2000; Rost and Revenaugh, 2001). This yields significant non-uniqueness in the models, but it does appear that the S-wave velocity reductions tend to be larger than the P-wave velocity

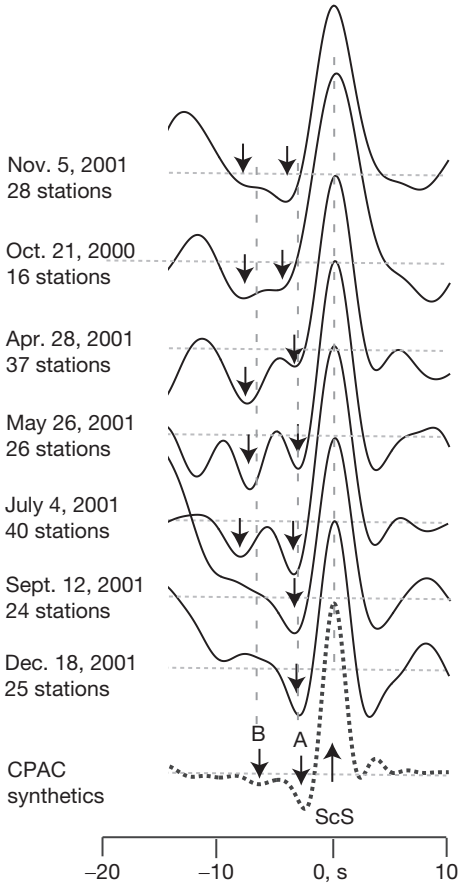

Figure 12 Stacks of the indicated number of deconvolved seismograms for several deep-focus events in the Tonga subduction zone, aligned on *ScS*, ordered by increasing event distance from California from top to bottom. Two stable negative amplitude peaks in the 10 s window before *ScS* are observed in the five closer events, with only one precursor being observed for the two more distant events. A stack of synthetics for a model CPAC with −1.1% and −3.8% discontinuities 70 and 30 km above the CMB, respectively. Direct S energy arrives 10–25 s before the windows shown. These data indicate that structure above the CMB is more complex than a single ULVZ. Reproduced from Avants M, Lay T, and Garnero EJ (2006a) A new probe of ULVZ S-wave velocity structure: Array stacking of ScS waveforms. *Geophysical Research Letters* 33: L07314, http://dx.doi.org/10.1029/2005GL024989.

reductions, and the density may increase by several to tens of percent.

1.22.7.2 Partial Melting and Chemical Anomalies

The strong velocity reductions in ULVZs are most easily explained by the presence of a melt component (Williams and Garnero, 1996), suggesting that either the mantle eutectic is exceeded at the hottest temperatures in the thermal boundary layer or there is infiltration of core material into the lowermost mantle. There is some correlation between locations of ULVZ patches and surface hot spots, which may further suggest a relationship between partial melting in D″ and large-scale upwellings (e.g., Garnero et al., 2007b; Lay et al., 2004b; Williams et al., 1998). Thermally induced rigidity variations can produce large shear velocity fluctuations relative to compressional velocities ($R = \mathrm{d}(\ln \mathrm{Vs})/\mathrm{d}(\ln \mathrm{Vp}) = 2.7$), whereas chemical variations tend to produce smaller values of $R \sim 1$–2. Partial melting can produce R-values of ~2.7–3.0 (e.g., Berryman, 2000; Williams and Garnero, 1996). The ratio of S-wave velocity anomaly to P-wave velocity anomaly in ULVZs has thus been of importance to assessing whether there is a significant chemical anomaly involved, even while partial melting appears to be the only way to approach the magnitude of the velocity decrements in ULVZs. Unfortunately, the ratio is very difficult to resolve given the many trade-offs in model parameters. Available results do favor a ratio closer to three than to one, but further analysis of P-wave velocity and S-wave velocity structure in the same spot using multiple seismic probes is needed to robustly resolve this issue. The observed ~10% P-wave velocity decrement associated with the ULVZ and the more poorly constrained ~30% S-wave velocity decrease imply melt fractions of between ~6% for 1:100 aspect ratio films of melt and ~30% for spherical melt inclusions (Berryman, 2000; Williams and Garnero, 1996).

The presence of a melt component in the ULVZ has important dynamic and chemical implications. Somehow the melt (if denser than the coexisting solids) does not simply percolate deeper to form a pure melt layer overlying the core. Alternatively, if the melt is buoyant, it would be expected either to rise to its depth of neutral buoyancy or to resolidify during adiabatic ascent (Hernlund and Jellinek, 2010; Hernlund and Tackley, 2007). This juxtaposition of solids and liquids thus implies that one of several possible effects occurs within the ULVZ: (1) the melt is not interconnected and thus is physically unable to efficiently drain from the surrounding solids; (2) the melt density closely matches that of the surrounding solids, so the buoyancy forces on the melt are insufficient to allow the melt to efficiently percolate; or (3) the average vertical convective velocity within the ULVZ is substantially greater than the velocity of melt percolation. Lay et al. (2004b) considered these scenarios, tending to favor the second or third as a means of developing a volumetrically extensive region with a melt component. Many ULVZ locations are on or within the margins of LLSVPs, suggesting some relationship to the thermal and dynamic processes in the LLSVPs. If the LLSVPs are dynamically configured by surrounding mantle flow and the ULVZs are configured by internal LLSVP dynamics, mapping of the structures provides first-order information on the location of deep mantle reservoirs (McNamara et al., 2010).

The presence of a melt component within the basal layer of the mantle is likely to have enhanced chemical interactions with the core through time and may be indicative of an enrichment of this zone in elements that are incompatible in mantle minerals near CMB pressures and temperatures. Thus, iron enrichment of D″ may have occurred through melt descent from above (e.g., Knittle, 1998), through subduction of iron-rich ancient oceanic crust (Dobson and Brodholt, 2005), or possibly through core interactions from below (e.g., Sakai et al., 2006). Recent work indicates that the core is undersaturated in Si and O, so the likelihood of significant diffusion of Fe into the mantle now appears low, and the lowermost mantle may instead be depleted in Fe (Ozawa et al., 2008). Mechanical mechanisms of core infiltration might still be plausible (e.g., Kanda and Stevenson, 2006; Otsuka and Karato, 2012). Labrosse et al. (2007) considered a model of ULVZ being

remnant of a much more extensive dense magma ocean above the CMB, which has cooled and solidified over time, concentrating partial melt into the ULVZ. Silicate melts in the deep mantle appear likely to be denser than surround material, allowing them to accumulate over time (e.g., Mosenfelder et al., 2009; Murakami and Bass, 2011; Thomas et al., 2012). The enrichment of radiogenic elements in D″ within the solidified basal magma ocean is generally consistent with a magmatic evolution for this boundary layer (Lay et al., 2004a,b): radiogenic element enrichment within the boundary layer has been suggested as a mechanism to reduce the required heat flux out of the outer core (Buffett, 2003).

A subsolidus mechanism to account for ULVZs involving postperovskite has been proposed by Mao et al. (2006a,b). Experiments indicate that postperovskite is tolerant of quite large amounts of Fe, up to 40% or higher, and that such large iron content has a dramatic effect on both S-wave and P-wave velocities. If postperovskite is stable at the hottest temperatures in the mantle at CMB pressures, this idea offers an alternative to having a dense melt component present. As noted earlier, there is large uncertainty in the absolute temperature in D″, and there is substantial uncertainty in the Clapeyron slope of the phase transition, so this possibility remains highly conjectural. Experimental measurements of sound velocities in $(Mg_{.16},Fe_{.84})O$ by Wicks et al. (2010) indicate that large uptake of Fe in magnesiowüstite results in pronounced seismic velocity reductions as well. Bower et al. (2011) proposed that iron-rich (Mg,Fe)O concentrations in localized patches account for the ULVZ. Further testing of these alternatives to partial melt fractions as an explanation for ULVZs is of high priority.

1.22.8 Lower Mantle Anisotropy

While the bulk of the lower mantle does not appear to have large-scale organized anisotropy, the D″ region has been shown to have extensive regions where shear-wave splitting occurs (see reviews by Kendall, 2000; Lay et al., 1998a,b; Moore et al., 2003; Nowacki et al., 2011). These observations have prompted increased consideration of the anisotropic crystallography of high-pressure phases likely to be present in the lower mantle along with what deformation mechanisms are likely to control the formation of fabrics (e.g., Karato, 1998; Stixrude, 1998). There remain substantial uncertainties in the nature of the anisotropy and its cause. Strong shear flows in the boundary layer may induce lattice-preferred orientation (LPO) of the anisotropic lower mantle minerals, but it is not immediately clear why this would not also hold for the overlying lower mantle. Sheared inclusions of chemical heterogeneities and pockets of partial melt may also play a role in generating the seismic anisotropy. The postperovskite phase transition may also be important. As observational and laboratory constraints improve, it is likely that modeling anisotropy in D″ will provide important constraints on the thermal and dynamic processes in the boundary layer, and impressive efforts in this direction have commenced (Walker et al., 2011).

1.22.8.1 Shear-Wave Splitting Observations

Observations of splitting for ScS phases have been made for several decades (e.g., Lay and Helmberger, 1983b; Mitchell and Helmberger, 1973; Rokosky et al., 2004), but observations of diffracted waves and wide-angle grazing S waves convincingly demonstrate that anisotropy is present in D″ (e.g., Ford et al., 2006; Garnero and Lay, 1997, 1999; Garnero et al., 2004a,b; Kendall and Silver, 1996; Lay and Young, 1991; Matzel et al., 1996; Maupin et al., 2005; Panning and Romanowicz, 2004; Ritsema, 2000; Ritsema et al., 1998a; Russell et al., 1998; Thomas and Kendall, 2002; Vinnik et al., 1989, 1995, 1998b). **Figure 8(c)** indicates the regions that have been studied in detail. All observations of D″ anisotropy are subject to uncertainties because of the limitations of the corrections for upper mantle anisotropy and the possibility of significant near-source anisotropy even for deep-focus earthquakes. Komatitsch et al. (2010) demonstrated that isotropic structure can produce apparent splitting for diffracted waves, so caution is required for diffracted data interpretations.

The large majority of observations involve horizontally polarized shear-wave components (SH) traveling faster through D″ than vertically polarized shear waves (SV) for grazing incidence or wide-angle reflections, with relatively large-scale regions of D″ displaying 0.5–1.5% anisotropy (e.g., Fouch et al., 2001; Garnero and Lay, 2003; Kendall and Silver, 1996; Ritsema, 2000; Rokosky et al., 2004; Thomas and Kendall, 2002; Thomas et al., 2007, 2011; Usui et al., 2005, 2008; Vinnik et al., 1998b; Walker et al., 2011; Wang and Wen, 2007b; Wookey and Kendall, 2008). While almost none of the studies have significant azimuthal raypath sampling, the observations are at least compatible with extensive vertical transverse isotropy, as may be caused by hexagonally symmetrical material with a vertical symmetry axis or fine-scale horizontal layering. The onset of shear-wave splitting appears to be linked to the S-wave velocity increase at the top of D″ in high-velocity regions (e.g., Garnero and Lay, 1997; Matzel et al., 1996), but the resolution of the depth extent of the anisotropy in the boundary layer remains very limited (Moore et al., 2003).

Localized observations of shear-wave splitting in D″ with SV velocities being higher than SH velocities have been reported, with localized upwellings in the boundary layer being invoked as one possible way to modify the symmetry axis for shape-preferred orientation (SPO) or LPO (e.g., Pulliam and Sen, 1998; Rokosky et al., 2004; Russell et al., 1998, 1999). Garnero et al. (2004a), Niu and Perez (2004), Maupin et al. (2005), Wookey et al. (2005a), Rokosky et al. (2006), Long (2009), and Nowacki et al. (2010) presented clear observations of azimuthal anisotropy from the analysis of S, SKS, and SKKS phases (**Figure 13**), with fast and slow waves mixed on the SH and SV components. Restivo and Helffrich (2006) did find that on the large scale, differential splitting of SKS and SKKS is relatively minor, with azimuthal anisotropy $< 2\%$ for extended regions.

1.22.8.2 Mineralogical/Dynamic Implications

Anisotropy compatible with the primary seismic observations of shear-wave splitting in D″ could be the result of LPO for a D″ mineral component or the result of SPO of chemical or partial melt components in a sheared boundary layer. A candidate major component of the lower mantle that may develop anisotropy with SH velocity faster than SV velocity in a horizontally sheared boundary layer is MgO or ferropericlase (e.g., Karato, 1998; Karki et al., 1999; Kendall, 2000; Long et al.,

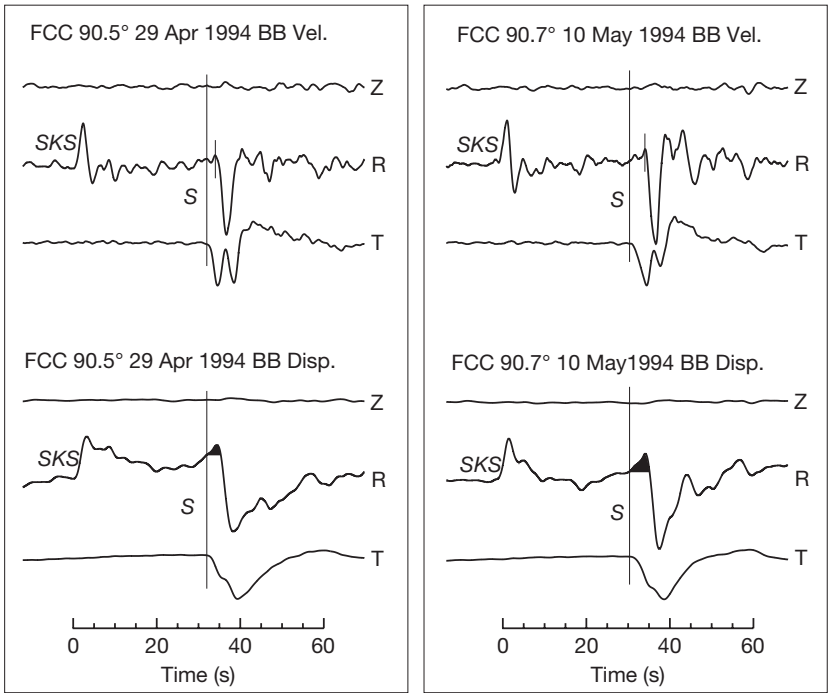

Figure 13 Three-component records from station FCC (Fort Churchill, Canada) for two deep South American earthquakes, showing ground velocity (upper plots) and ground displacement (lower plots) spanning the SKS and S arrivals. Corrections for receiver lithospheric anisotropy have been applied (note that no SKS energy is seen on the transverse component), and the Z and R rotations are to the wave front normal and wave front parallel directions for the SKS arrival, respectively. The arrival time of S is indicated by the vertical lines. The small reverse-polarity upswing at the beginning of the S wave on the radial components of the displacement seismograms is colored in black. This feature is easily missed in the velocity records, and one is tempted to pick a sharp correct-polarity negative arrival as the first SV arrival (small ticks). The reverse-polarity energy is produced by azimuthal anisotropy, either in D″ or possibly near the source, which couples the fast arrival to the R and T components. Reproduced from Maupin V, Garnero EJ, Lay T, and Fouch MJ (2005) Azimuthal anisotropy in the D″ layer beneath the Caribbean. *Journal of Geophysical Research* 110: B08301, http://dx.doi.org/10.1029/2004JB003506).

2006; Mainprice et al., 2000; Marquardt et al., 2009a; Stixrude, 1998; Yamazaki and Karato, 2002), whereas low-velocity lamellae composed of partially melted crust or other chemical heterogeneities are also possible causes of such anisotropy (e.g., Fouch et al., 2001; Kendall and Silver, 1998; Moore et al., 2003; Wysession et al., 1999). Anisotropy of perovskite has also been quantified (e.g., Mainprice et al., 2008). McNamara et al. (2001, 2002, 2003) used thermal convection models to compute variations in temperature and stress regime that might result in the localization of dislocation creep that favor LPO in some areas and diffusion-dominated deformation in others that would require SPO to account for any anisotropy. These dynamic calculations indicate that conditions favorable for mid-mantle anisotropy may exist in downwellings, but as yet, there is no clear evidence for anisotropy in the bulk of the mid-mantle (e.g., Kaneshima and Silver, 1995; Meade et al., 1995).

The anisotropic properties of postperovskite may further explain the strong association between regions with a lower mantle S-wave velocity discontinuity and regions with S-wave splitting that is stronger than observed in lower-velocity regions. Stackhouse et al. (2005b) computed the anisotropic properties of postperovskite and considered the propensity for developing LPO compatible with seismic observations. It appears that postperovskite has more favorable properties than perovskite for acquiring LPO in D″ (Nowacki et al., 2010, 2012; Wookey and Kendall, 2007). The deformation of postperovskite and analog materials also supports the notion that postperovskite may acquire anisotropic fabrics in the lowermost mantle (Carrez et al., 2007b; Merkel et al., 2006, 2007; Miyagi et al., 2010, 2011; Niwa et al., 2007, 2012; Okada et al., 2010; Walte et al., 2009; Wenk et al., 2011; Yamazaki and Karato, 2007; Yamazaki et al., 2006; Yoshino and Yamazaki, 2007; Zhan, 2011). The size of the D″ discontinuity may exceed the velocity increase for the postperovskite phase change on average, and anisotropic properties may be required to match the observations (Murakami et al., 2007b).

1.22.9 Small-Scale Heterogeneities

The emphasis in the foregoing sections has been on intermediate and large-scale structure, as this is most readily resolved by tomographic and waveform modeling procedures. However, as is true of the lithosphere, key dynamic and chemical structures exist in D″ on scales below the limit of deterministic resolution using seismic waves with wavelengths longer than 10 km or so. Very fine structure will scatter seismic energy, and statistical attributes of the structure can be constrained using various approaches.

1.22.9.1 Scattering in D″

Small-scale variations in D″, with about 1% heterogeneities on scale lengths of about 10 km, are revealed by scattered P-wave signals. This has been demonstrated by the analysis of short-period precursors to PKP phases (e.g., Bataille and Flatté, 1988; Bataille et al., 1990; Brana and Helffrich, 2004; Cao and Romanowicz, 2007; Cleary and Haddon, 1972; Cormier, 1999; Doornbos, 1976; Garcia et al., 2009; Haddon and Cleary, 1974; Hedlin and Shearer, 2000; Hedlin et al., 1997; Miller and Niu, 2008; Thomas et al., 2009) and P′P′ (Wu et al., 2012). The small-scale structure is also analyzed using diffracted coda waves (e.g., Bataille and Lund, 1996), PKKP reflections (e.g., Earle and Shearer, 1997; Rost and Earle, 2010), triplications (e.g., Kohler et al., 1997), and scatterer migrations (e.g., Thomas et al., 1999). Some studies purport to show evidence for thin layers of anomalous properties or lamellae in the boundary layer (e.g., Lay and Helmberger, 1983b; Thomas et al., 1998; Weber, 1994). The structural heterogeneities involve scale lengths of a few to tens of kilometers, with various estimates of velocity fluctuations of a few to 10%. It has generally been believed that the levels of heterogeneity increase in D″ relative to the overlying mantle, but there is evidence that small-scale structure in D″ is not distinctive from that throughout the mantle (e.g., Hedlin et al., 1997). Nonetheless, it is clear that some of the strongest scattering, involving much larger velocity heterogeneities, does arise within D″ (Vidale and Hedlin, 1998; Wen and Helmberger, 1998), and this is likely associated with the patchy ULVZ just above the CMB. The bandwidth of the signals used in scattering analyses controls the sensitivity to scatterers of different dimensions, and the analysis of broadband data indicates a rich spectrum of scattering scale lengths in D″.

Cormier (2000) had developed the perspective of D″ being a transition in the heterogeneity spectrum of the lowermost mantle, with a relatively 'red' spectrum, having substantial power at long wavelengths but still significant strength at short wavelengths. It is plausible that small-scale structure also exists on the core side of the CMB, concentrated in topographic highs (e.g., Buffett et al., 2000; Garnero and Jeanloz, 2000; Rost and Revenaugh, 2003).

1.22.9.2 Core–Mantle Boundary Topography

Given the complexity of structure at all scales in D″, it is not surprising that large uncertainty remains as to whether there is much topography on the CMB itself. Long-wavelength topography of the CMB was proposed by Creager and Jordan (1986b) and Morelli and Dziewonski (1987) based on studies of bulletin PcP and PKP arrival times, but it has been demonstrated that allowing for strong heterogeneity in D″ and the limited resolution of the available data make CMB topography models very uncertain (e.g., Doornbos and Hilton, 1989; Garcia and Souriau, 2000; Obayashi and Fukao, 1997; Pulliam and Stark, 1993; Rodgers and Wahr, 1993; Sze and van der Hilst, 2003). As models for the entire mantle improve, this may prove to be a solvable problem, and it is a critical one, for CMB topography plays a major role in estimating the extent of mechanical coupling between the core and the mantle. For imaging shorter-wavelength topography of the CMB, the primary approach has involved travel time fluctuations and precursors to underside reflections of internal core reverberations (PKKP). These phases provide an upper bound of about 100 m topography on 10 km scale lengths (e.g., Bataille and Flatté, 1988; Chang and Cleary, 1978; Doornbos, 1974, 1980; Earle and Shearer, 1997, 1998; Tanaka, 2010). Nutation data bounds very long-wavelength topography on the CMB to a few hundred meters (Defraigne et al., 1996). The calculations of topography induced by flow (e.g., Lassak et al., 2007; Yoshida, 2008; Youngs and Houseman, 2007) provide testable predictions that can be evaluated by using seismic observations (Lassak et al., 2010).

1.22.10 Conclusions

Any attempt to characterize the knowledge of the lower mantle and D″ region can only provide a snapshot of a rapidly evolving, even exploding topic. Interdisciplinary progress in mineral physics theory and experimentation, geodynamics, and geochemistry resonates with advances in seismological imaging, redefining conceptual models with remarkable rapidity. One decade's 'superplumes' become the next decade's 'superpiles,' with major shifts in perception of the roles played by seismically detected heterogeneities. This is both stimulating and unsettling, with our understanding of the mantle system acquiring more and more levels of complexity. The extensive citations provided here are intended to help the reader penetrate into the deluge of findings from multiple disciplines addressing lower mantle and D″ topics. This is an increasingly daunting task with a very distributed literature, and there is no slowing down of activity as yet.

So, what lies ahead? There continues to be great potential to make major advances in our understanding of the thermal regime in the lowermost mantle if the postperovskite phase transition is shown to be the correct explanation for the D″ discontinuity. This is because a phase transition can be calibrated in actual P–T space, greatly reducing the uncertainty in temperature estimates currently obtained by extrapolation over thousands of kilometers in depth. Parallel efforts in mineral physics and seismology can advance this topic much as they have advanced our understanding of transition zone conditions; however, it has become clear just how important the role of precise chemistry of each mineral phase is, compounded by the effects of iron spin transitions.

Increasing densification and accumulation of seismological data sets is enabling new approaches such as migration to be applied to deep mantle targets. While coverage is, and will remain, embarrassingly limited compared to exploration industry data sets, the advantage of generally parameterized migrations for rough structure has already been established and promises to reveal important structural characteristics in the lower mantle. Large data sets are also critical to one of the persistent challenges in deep Earth imaging, separating source, deep, and receiver contributions to the signals. Studies of lower mantle scattering, lower mantle anisotropy, and lower mantle stratification are all plagued by near-source and near-receiver signal-generated noise. Improved suppression of these effects by combining empirical filters and stacking approaches holds much promise for improving seismological resolution of deep structure. The large data sets enable full waveform inversion

approaches to some extent, although the problem in deep mantle applications is the severe limitation of azimuthal path sampling, so it is not clear yet whether there is any true gain to be had by waveform inversions over imaging methods. It is clear that expanding global coverage of seismic observations, particularly by increased long-term operation of ocean floor recording systems, is essential for better characterizing deep Earth structure globally. With new procedures such as noise correlation allowing deep structure to be probed between all pairs of stations (e.g., Lin et al., 2013), each new observation point provides extensive new probing of deep mantle structure below each station.

Seismological structures in the deep mantle LLSVPs have been shown to have lateral gradients as strong as radial gradients, and the search for steeply dipping interfaces using azimuthal data gathers has proved fruitful. Approaches to quantifying three-dimensional structures for poorly sampled wave fields require both efficient 3D computational tools and new strategies for modeling, and significant progress is being made in this arena. Approaches based on iterating from initial tomographic models have shown some success, but the wave field complexity often involves smaller scales than constrained by tomography. One cannot help but feel that we have still only scratched the surface of the complex regime that likely exists in the deep mantle. Much work remains.

1.23.1 Introduction

The Earth's core represents 16% of the volume of the Earth and more than 30% of its mass. It is composed of an iron alloy that incorporates light elements and nickel. At the center of this wide ocean of iron, the solid inner core, of about the size of the moon, represents only 4.3% of the volume of the core and $<1\%$ of the volume of the Earth. It results from the freezing of the liquid core during the cooling of the Earth, with a strong depletion in light elements. The core plays a very important role in Earth physics and chemistry. However, despite its impact on many physical processes such as magnetic field and the Earth's rotation, which have been investigated for centuries, the core has been detected very late, in 1906, when the seismological observation of the deep Earth became possible. Since then, important advances have been made, combining observations, laboratory experiments, and theoretical modeling. But the core remains enigmatic. If some of the core

properties are now firmly established, many others are still controversial. This chapter will attempt to give a survey of the present state of the art, trying to give a degree of confidence to the various results.

Before going through the details of the core structure, it is useful to recall some basic information concerning the core, which in addition shows its importance in the planet Earth system. The core is governed by complex systems of relations implying thermodynamics, hydrodynamics, geomagnetism, and geochemistry. Advances and results concerning these different disciplines may be found in other chapters of this treatise, in particular **Chapters 2.06**, **3.10**, **8.02**, **8.04–8.09**, **8.12**, **8.13**, **9.03**, and **9.08**.

The core forms very early in the history of our planet, as revealed by the analyses of lead and uranium mantle isotopes and other radionuclide chronometers and by the presence of a magnetic field in the oldest rocks of the Earth, 3.5 Ga old. It is generally accepted that the inner core formed by crystallization of the liquid core. Some thermodynamic arguments favor a rather young inner core, about 1 Ga old, but this is still open to discussion.

Convection in the liquid core is at the origin of the main part of the magnetic field. From this point of view, the core is essential to the life, as it protects the Earth from the solar wind. Numerical simulations of the Earth geodynamo show that the inner core has probably a stabilizing role for the magnetic field, as it prevents frequent geomagnetic reversals.

The boundary of the core with the silicate mantle, the core–mantle boundary (CMB), is a place of thermal, dynamic, and probably chemical exchanges. In particular, the exchange of angular momentum influences the Earth's rotation. At the inner core boundary (ICB), the freezing of the liquid iron alloy occurs with a depletion of the light elements that are present in the liquid core. The ICB is thus also an important place for chemical and energy exchanges. Heat sources linked to inner core growth, including latent heat and gravitational energy, are essential for powering the geodynamo and are important factors in the thermal history of the Earth.

In what follows, we will only consider the aspects relevant to the structure of the core, giving a particular importance to seismology, which has provided most of the results obtained today about its internal properties. After a brief historical review, we will present the most usual tools used in core seismology. The radial structure of the core will then be investigated, paying particular attention to the core boundaries. Then, a large section will concern the inner core, for which different properties will be considered: its rigidity; its anisotropy for both velocity and attenuation; its hemispherical dichotomy, which also concerns both velocity and attenuation; and its possible differential rotation or oscillation with respect to the mantle. We will end this chapter with the still open questions and future challenges.

1.23.2 The Discovery of the Core
